Aim of deconstruction and recycling of construction materials and buildings is to drastically reduce the deployment and consumption of primary non-renewable construction materials. Actual barriers in this industry can be found in Nakajima and Russell (2014). Furthermore, challenges faced to design for deconstruction make it difficult for architects to incorporate material recovery procedures into the initial building design (Hobbs & Adams (2012)). In the following different challenges are further described and analysed.

3.1 Technical challenges

Technical challenges of the deconstruction and recycling industry are often caused by unknown material qualities in existing buildings that are deconstructed. Establishing the structural performance of reused components can be perceived to be difficult by engineers who will be hesitant to use salvaged structural components unless they have been tested in accordance with current standards. This hampers reuse and recycling options. Hence, relevant technical developments to enhance reuse, recycling and waste tracking are economical material sampling methods for decontaminations and material quality measurements and documentation. These would enable fast determination of material quality and subsequent options of recycling material usage based on regional material demands. Within this context, actual knowledge on regional demands is required to locally reuse materials, which leads to one issue of organizational challenges (see section 3.4).

Furthermore, the use of non-reversible joints can make the deconstruction of building components difficult or impossible and therefore state technical challenges of design for deconstruction. For instance, in North America wood frame dominates residential low-rise building, which are often difficult to dismantle due to a large number of fasteners (Falk and Guy (2007); Davis (2012)). Framing members such as stick framing or trusses for roofs can be dangerous to remove and may require special equipment or bracing during the deconstruction process. The use of mechanical and easier to loosen joints might reduce this technical challenge.

Also, innovative approaches for automated separation and decontamination of building elements e.g. via robots or self-controlling machines are required. They seem promising for instance, in the context of separation of outer walls thermal insulation composite systems, separation of layer composites as well as decontamination in contaminated sites and in decommissioning and deconstruction of nuclear power plants, such as the system MAFRO (Baulinks (2015)).

Furthermore, technical development of cost effective methods of raw materials sorting and of material processing plants are required to produce secondary raw-materials of constant quality. This also includes optimization of existing processing plants.

Further technical challenges exist in the automation of deconstruction processes, such as the acquisition of building information, processing of analogue and digital building information, operative project planning, emission management or site surveillance and control, e.g. via sensors. The application of digital building models and sensors onsite would enable planners and deconstruction companies to automatically plan, track and document project performance and related impacts on employee’s health or the local environment, such as adjacent neighbours or buildings. However, the demolition industry seldom adapts digital building models and planning methods, yet. At the moment the digitalization is limited to digital building documentation via Word/Excel on tablets.

Moreover, good examples demonstrating effectiveness of design for deconstruction, of selective deconstruction, material recycling and reuse are required to overcome technical challenges.

3.2 Economic challenges

Major economic challenge is the lack of economic incentives to use recycling materials in new constructions in most countries. Reasons are comparably cheap raw materials and low costs of

construction units, expensive material sampling methods, differing material qualities of recycling materials and temporal and spatial divergence of demand and supply.
In many countries the main structural building components are often not salvaged due to a perceived lack of demand. Only single, high value, quick sale items are usually collected by selective deconstruction and often sold to a heritage market. This problem is one of both, supply and demand. Retailers do not carry products that are not demanded and consumers do not buy products they do not know. This is closely related to the awareness of the value of reclaimed building components. Sampling of built-in materials or building elements and tests of reclaimed components for structural integrity are costly and impede material quality determination and material reuse/recycling options. Although there are some national and regional online marketplaces and platforms for recycling materials and used building elements (in Germany on national[3] and regional[4] level; in Austria[5]; Canada[6]; Netherlands[7]), the comparability and quality assurance of the offered materials/elements are not always given. Some clients even specify that they want all "new" materials. Here the liability of designers or recyclers can be a significant concern. "Without legislative action to create an artificial economic driver, the current market for deconstructed material is […] to remain economically feasible" (Nakajima and Russell (2013)). Widely spread recommendations among countries are to "encourage financial burdens on the landfill process through tipping fees or taxes" to force reuse/recycling or "provide financial incentives for efficient designs that facilitated end of life deconstruction" and recycling (Nakajima and Russell (2013)).
Furthermore, the demand is low, as reused building components are currently not available. More work is required by the design team to anticipate material requirements and identify potential sources. The question is, if there is enough of a single used component type to meet the demands of a new construction project. Then, design would need to be adaptable. Furthermore, production costs of recycled concrete aggregate vary depending on its use. Concrete components of existing buildings may need to be stored, moved and transported between sites and locations that might result in higher costs for new construction projects. Moreover, recycled aggregates might contain contaminant residuals, which reduce the compressive strength of the aggregate by up to 18% (Chini, et al (2001)). If the quality of recycled aggregate is lower than the virgin aggregate materials, the price should also be lower. However, the cleaning, processing, inspection, storage, and sale of recycled aggregate can result in higher costs than virgin aggregate. Other materials such as timber are extremely cheap to buy new and clean (e.g. in North America). Also, they are difficult to separate from other building components. Hence, there is very little economic perspective in recycling these materials.
In general, many industry professionals state that deconstruction result in higher overall costs for a project than traditional demolition and landfilling. Without a clear market and value for salvaged products little attention is paid to maintaining quality of demolition products.

[6] http://www.owe.org/, http://www.greenguide.com/exchange/
[7] http://www.oogstkaart.nl/oogstkaart/

Moreover, according design for deconstruction additional time is often required for architects and engineers to include the added features to facilitate building deconstruction.

3.3 Ecologic challenges

Major ecologic challenges are that information on the life cycle of products as well as planning for end of service life are rarely considered and not yet mandatory at the building design stage (design for deconstruction). Values for use of reclaimed materials are mainly aesthetic and there are health concerns regarding the use of recycled material, which might contain hazardous substances. Environmental benefits are secondary.

Environmental product declarations (EPDs) (ISO (2006)) quantify ecologic information on the life cycle of products, based on Life Cycle Assessment (LCA) studies of independent institutions. EPDs represent a complete, robust and scientifically validated source of information of the environmental impacts of products along their life cycle. Even though they are not yet mandatory, EPDs are defined as a source of quantitative information on product life cycles in a standard way by the European Commission (EC, 2003). When available, EPDs can be used to assess the use of resources and the impact of construction works on the environment, according to the Construction Products Regulation (CPR) (EP (2011)). EPDs of construction products based on recent European standards (CEN (2011), (2013)), with the environmental assessment of construction waste flows, can be an important source of data for decision-making at the end-of-life of building materials and to 'close the loop' in their life cycle. Nevertheless, most EPDs are cradle to gate, including recycled content but no waste management processes or "recyclability" except in uses of steel and other metals, where recycling is more or less guaranteed. Hence, these gaps in reused/recycled materials for standards of life cycle stages, inventory data and allocation rules are major issues in the adoption of LCA.

Furthermore, if design for deconstruction would become a requirement or common practice, the likelihood of major portions of the building being salvaged can be greatly improved and the environmental impacts of that stage can decrease.

3.4 Organizational and educational challenges

A major organizational and educational challenge is a lack of knowledge by designers and builders on issues of component reuse. Designers are often not aware of supply sources and of actual materials. Although this issue has been highlighted by many green building rating programs, it is not highlighted in education programs, which tend to focus on waste reduction on site. The producer responsibility in the construction industry is not well established, and return of materials/components to their source only occurs if they have economic value. Many residential constructions are not big enough to fall under the regulations that do exist. Therefore, the client is not forced to provide a waste management plan and any demolition waste is most often sent to landfill, but may implement material reuse where gains can be created. Furthermore, this lack of awareness makes demolition crews more likely to work recklessly and simply remove components as quickly as possible. Deconstruction and reuse still tend to be a niche activity. Although there are various resources available including scattered retailers and deconstruction practitioners, the mainstream industry seems unaware of the possibilities of reuse and the value of the existing materials. Within this context there is also a lack of consistent standards that include deconstruction. Hence, it is difficult to provide specifications for carrying out deconstruction and/or supervising the deconstruction process.

Besides, there are other organizational challenges due to logistics and scheduling. Demolition is usually on the critical path and contractors are under time pressure. Ironically a building may have sat derelict for years but as soon as a new project is planned for the site there is very little time to carefully deconstruct the building. Hence, deconstruction as a slower process to remove the building is not performed. Additionally, often space and cost constraints prohibit the use of sorting bins for different materials on site. Furthermore, infrastructure is needed to collect, transport, store, and prepare salvaged components. But this infrastructure is rarely available.

Moreover, there is often a lack of cooperation among all parties, including owner, designers, contractors, subcontractors, and waste haulers about resource stewardship. If any of the interested parties do not fully grasp the purpose of deconstruction, it can hinder the entire process. A thorough understanding of the project's plan and goals are often not shared with all parties are not monitored.

3.5 Political/legal challenges

At present there are no legal requirements in any country for clients or contractors to consider deconstruction at the design stage. Furthermore, the obligatory use of recycling materials in the construction sector is not implemented in many countries yet except for concrete in Switzerland and the monetary incentives against landfilling are not high enough. Although many central and local governments are supportive of reducing waste, the issue of reuse is not in the focus of decision makers, such as politicians and clients. Sometimes it is even a threat to existing resource supply industries.

4. Leading national and global initiatives on deconstruction and construction materials management

Finishing the research in state of the art of demolition and reuse and recycling of construction materials, on-going national and global initiatives in the area of deconstruction and reuse/recycling of construction materials are summarized. The entities and stakeholders in charge of these initiatives and developments are associations, research centres and countries. The first type of initiatives is legal actions - such as specific regulations developed worldwide and related to construction material stewardship. Most of them are promoted by national governments. A summary of these initiatives based on the scope of this research is presented in Table 4 (own representation) for raw material extraction, material recycling process and use of recycled C&D material, respectively. The second type are global initiatives with a broader impact, for instance at the European level, such as the European Demolition Association (EDA (2015)). The promotion of European standards on demolition techniques and on recycling of demolition waste are major objectives of this institution.

Table 4: Regulatory initiatives at a national level related to material recycling processes, raw material extraction and the use of recycled C&D material based on the scope of this report

Country	***Specific regulation and content***
Canada	- *Canadian Standards Association CSA Z782-06:2012. guide for deconstruction, disassembly and adaptability of buildings* - *Construction and Demolition Debris Deposit Program of San Jose: regulation on deposits of construction and demolition debris* - *Provincial aggregates royalty fees: royalty fees per tonne of aggregate extracted for instance in Ontario, British Columbia, Alberta and Quebec* - *Environmental Protection Act (EPA) Regulation 102/94. Requirements for waste audit before demolition, source separation (recycling) program*
Denmark	*Tax on extracted raw materials(sand, gravel, stones, peat, clay and limestone) and on waste.*
Germany	- *Closed Substance Cycle Waste Management Act (KrW-/AbfG (2000)): basic principles for waste management and closed loop recycling strategies. Waste management hierarchy - the first goal is waste prevention and avoidance* - *Ordinance about waste treatment (NachwV (2006)): way and scope to proof waste disposal and recycling* - *General technical specifications in construction contracts - demolition and dismantling work (ATV DIN 18459(2012)): extraction, storage and transportation of deconstruction materials/components based on the European Waste Catalogue (EWC)* - *Planned "substitute building materials ordinance". Actual draft as at October 31st 2012: nationwide regulations on mineral alternative construction materials produced out of/ resulting from recycled construction materials* - *Standard of "aggregates for concrete and mortar - part 100: recycled aggregates (DIN 4226-100 (2002)): quality of recycled aggregates and the composition of construction materials with portions of recycled aggregates (concrete and masonry)*
Israel	- *Green Building Standard: voluntary principles for on-site waste management and closed loop recycling strategies* - *EPA: Municipal Solid Waste Landfill Regulations. operation and management of municipal solid waste landfills* - *Mining and Quarrying laws and regulations: planning and operation of quarries, increase efficiency of raw material extraction, such as aggregates, sand and cement* - *Requests for proposals and promoting obligatory use of recycled C&D waste: promotion of policy aiming at obligating contractors to use recycled C&D waste in buildings projects and public infrastructure*
Netherlands	*The Dutch building materials decree: quality criteria for the application and re-use of stony materials and earth used as building materials (Eikelboom et al. (2001)). Reduction of waste material disposal and raw material extraction (Hendriks and Raad (1997)).*
Portugal	- *Guide for the use of coarse recycled aggregates in concrete (LNEC Specification E 471-2009):requirements for coarse recycled aggregates used in concrete (according EN 12620)* - *Law-decree Nr.73/2011, July 17th: mandatory use of recycled materials in public construction*
Sweden	- *Tax on natural gravel: substitution of natural gravel use (Söderholm (2011a), (2011b)).* - *Regional material inventories of natural gravel and alternative materials (Söderholm (2011b)).* - *Quality standards for road construction materials and tender bonus: to tender construction firms to use crushed rock instead of gravel (Söderholm (2011b)).*
Switzerland	*Recycling of aggregates (SN 640740, SN 640743 (1993)): obligatory recycling and use of RC concrete in new construction*
United Kingdom	*Taxes on aggregates: taxes on all extracted aggregates and imports (with the exception of recycled aggregates: sand, gravel and crushed rock used in construction)(Söderholm (2011b)).*
USA	- *Municipal C&D recycling rate requirements in Chicago and Washington* - *Municipal mandatory C&D recycling, materials separation and deconstruction and reuse requirements in Seattle, Portland and Chicago* - *C&D materials landfill ban in Massachusetts*

5. Conclusion

The analysis of the state of the art of demolition and reuse and recycling of construction materials shows that the leading institutions are very fragmented and leading processes are diverse. This reflects the actual structure of the construction and demolition industry, which is

dominated by small and medium sized enterprises and includes diverse stakeholders and processes. Consequently, especially international activities are difficult to implement, as shown by the analysis of leading national and global initiatives.
The major aim of deconstruction and recycling of construction materials is, to drastically reduce the deployment and consumption of primary non-renewable construction materials. The identified challenges related to this aim show that current activities are highly driven by costs. Particularly, country specific regulatory initiatives are identified to meet these challenges.

FLEX 3.0: an Instrument to Formulate the Demand for and Assessing the Supply of the Adaptive Capacity of Buildings

Rob P. Geraedts and Matthijs Prins

Faculty of Architecture, Delft University of Technology, Netherlands
Email: r.p.geraedts@tudelft.nl

Abstract

Market developments show increased demands for flexibility and sustainability by users and owners of buildings. A direct connection can be made between adaptive building and sustainability. The longer a building can keep its functional life cycle instead of becoming vacant or being demolished, the more sustainable a building will be. One way of looking into this phenomenon is the more a building is flexible and able to adapt to changing user demands, the longer it will keep its functional life cycle. In 2014 a paper was presented at the International Union of Architects World Congress UIA2014 in Durban SA, titled Adaptive Capacity of Buildings. A report was given of an extensive international literature survey and the development of a method to determine the adaptive capacity of buildings. In total 147 flexibility indicators were described with accompanying assessment values. The most important recommendation for the next step was the development of an easy to use assessment method in practice with a limited number of important adaptability performance indicators.
Further research led in 2015 to a renewed assessment method with 83 indicators, clustered in five layers with different life cycles. This method was called FLEX 2.0 and a derived version was called FLEX 2.0 LIGHT with only 17 of the most important indicators. This was presented in 2015 at the CIB Conference - Going North for sustainability in London. At the same time this method was used in two separate research projects for an evaluation with experts in practice. One research project concerned the development of school buildings; the other project was related to the development of office buildings. The main conclusions and recommendations of both research projects to evaluate the FLEX 2.0 method in practice with two different types of real estate will be described in this paper. Questions will be answered about the differences and similarities between the two different categories of real estate when using this flexibility assessment method. This will lead to some important conclusions for the next version of the method: FLEX 3.0. Finally a renewed framework for this next version will be presented.

Keywords: assessment instrument, adaptive capacity, building, flexible, sustainable

1. Introduction

Market developments show increased demands for flexibility and sustainability by users and owners of buildings. A direct connection can be made between adaptive building and sustainability. The longer a building can keep its functional life cycle instead of becoming vacant or being demolished, the more sustainable a building will be. One way of looking into this phenomenon is the more a building is flexible and able to adapt to changing user demands, the longer it will keep its functional life cycle. In 2014 a paper was presented at the International Union of Architects World Congress UIA2014 in Durban SA, titled Adaptive Capacity of Buildings (Geraedts 2014). A report was given of an extensive international literature survey and the development of a method to determine the adaptive capacity of buildings (Geraedts 2013). In total 147 flexibility indicators were described with accompanying assessment values (Hermans 2014). The most important recommendation for the next step was the development of an easy to use assessment method in practice with a limited number of important adaptability performance indicators. Further research lead in 2015 to a renewed assessment method with 83 indicators. They were clustered in five layers with different life cycles. This method was called FLEX 2.0 and a derived FLEX 2.0 LIGHT version with only 17 of the most important indicators. This was presented in 2015 at the CIB Conference - Going North for sustainability in London (Geraedts 2015).

At the same time in two separate research projects the method FLEX 2.0 was used for an evaluation with experts in practice. One research project concerned the development of school buildings (Carlebur 2015); the other project was related to the development of office buildings (Stoop 2015). The main conclusions and recommendations of both research projects to evaluate the FLEX 2.0 method in practice will be shortly described in this paper. Questions will be answered about the differences and similarities between the two different categories of real estate when using this flexibility assessment method. This will lead to some important conclusions to develop the next version of the method: FLEX 3.0. Finally a renewed framework for this next version will be presented.

2. Previous Developments

2.1 Determination Method for Adaptive Building

Definition of Adaptive Capacity

The adaptive capacity of a building includes all characteristics that enable the building to keep its functionality through changing requirements and circumstances, during its entire technical life cycle and in a sustainable and economic profitable way. The adaptive capacity is being considered as a crucial component when looking into the sustainability of the real estate stock (Hermans 2014).

Adaptive Capacity Determination Method

In 2014 a method for determining the adaptive capacity of buildings has been developed after an extensive survey of international literature on the characteristics, definitions and assessment instruments of adaptive building and on boundaries of adaptive capacity, sustainability and financial business cases for real estate. The literature survey has resulted in a number of basic schemes with relevant flexibility indicators and their mutual relationships. Next to the literature survey, a substantial number of experts from practice have been consulted. The basic schemes formed the input for discussions in two different expert panels: one with representatives of the clients (demand side) and one panel with representatives of construction companies and suppliers (supply side) in the construction process (Geraedts 2013, Hermans 2014). The adaptive capacity method consists of three different modules:

1. The determination of the adaptive capacity.
2. The determination of the financial-economic viability.
3. The determination of the sustainability impact of the measures chosen.

FLEX 1.0: 147 Indicators to determine the adaptive capacity

In the further research only the first module was elaborated: the adaptive capacity of buildings (the AC Method). This method delivered a clear insight in and an overview of aspects that needed to be taken into account when assessing the adaptive capacity of buildings. The method combined existing knowledge on flexibility and sustainability (Berg 1981, Houtsma 1982, Geraedts 1989, REN 1992, Geraedts 1998, Geraedts 2001, Geraedts 2007, Schneider 2007), Beadle 2008, Geraedts 2009, Wilkinson 2009, DGBC 2013) amongst others into one overview of important aspects to determine the adaptive capacity.

For the owner of a building in total 36 different indicators were formulated with associated values for assessing the spatial/functional flexibility characteristics, and 49 different indicators to assess the construction/technical flexibility characteristics of a building. For the user of a building in total 29 different indicators were formulated with associated values for assessing spatial/functional flexibility characteristics, and 33 different indicators for assessing construction/technical flexibility characteristics. The total addition finally led to 147 indicators to determine the adaptive capacity of a building from an owners and a users point of view. It was the first step in the development of instruments to assess specific projects. Although it was not mentioned as such, one can identify this first version with the 147 flexibility indicators as FLEX 1.0.

The steering group behind this research project and the two already engaged expert panels played an important role for addressing the next research aim: the translation of this first developed instrument into a more accessible and easy to use instrument in the daily construction practice, with less indicators to deal with. This resulted in a renewed condensed method called FLEX 2.0 that will be briefly described in the next paragraph.

2.2 FLEX 2.0 and FLEX 2.0 LIGHT

Combining and clustering in five layers

First of all the double flexibility indicators described for the owner and the user of the building as well, were combined together. To structure and cluster the remaining large number of possible indicators any further, use has been made of the distinction in five layers with a different life cycle of the building and its environment (Brand 1994). As a consequence the number of flexibility indicators in FLEX 2.0 was reduced from 147 to 83 indicators, spread over five layers: Site, Structure, Skin, Facilities and Space plan/Finishing (Geraedts 2015).

Structure of FLEX 2.0: General requirements

To be able to actually use the adaptive capacity of a building or to change the use of a building is it necessary to recognize a number of common important preconditions. Especially some legal, organizational and common constructional preconditions have to be mapped before further actions can take place. Is it possible to change the function of the building or to extend the building according to the actual development plan of the local government? What is the general technical condition of the building, what is the age, when was the last renovation of the building, what type of user utilized the building?

Assessment level, weighting and scores

In this method values are given for each assessment aspect of flexibility performance indicators. Next to the indicator, the related assessment values and remarks, a column is shown to give a personal weight to the various indicators (varies from 1 = not important to 3 = very important) and finally a column to mark the score or level of the specific indicator concerned. There are four possible values for the score: 1 = Bad, 2 = Normal, 3 = Better, 4 = Best. Figure 1 shows an example of the four assessment values of indicator nr.11: Surplus of free floor height. The final score is calculated by multiplying the assessment value and the weighting factor for that indicator (see example in figure 2).

11 Surplus of free floor height	Assessment values of the free floor height	Remark	Weighting	Score
How much is the net free floor height?	1. < 2.60 m (Bad) 2. 2.60 - 3.00 m (Nromal) 3. 3.00 - 3.40 m (Better) 4. > 3.40 m (Best)	The higher the free floor height, the better a building can be rearranged or transformed to other functions, the better a building can meet to changing demands of facilities and the quality of the building or units.	1 = less important 2 = important 3 = very important	Score = assessment x weighting

Figure 1: Example of the four assessment values of flexibility indicator nr. 11: Surplus of free floor height, the assessment values, remarks, weighting and score (Geraedts 2015)

FLEX 2.0 LIGHT: The 17 most important indicators

After the clustering of 143 indicators to 83 indicators, in the next step a second clustering was carried out to find a limited number of the most crucial indicators. This lead to FLEX 2.0 LIGHT with 17 indicators in total, a very easy and fast to use instrument to assess the adaptive capacity of a building. Figure 2 shows an example of a fictive assessment of a certain building with FLEX 2.0 LIGHT. Each of the 17 indicators has been given a weight relative to the other indicators (weighting 1 - 3). Also each indicator is assessed (assessment level 1 - 4). This leads to a score per indicator and summed up to a total Adaptivity Score. At the same way a theoretical minimum score can be found of 17 and a maximum score of 204. With these two borders a class table can be made with five different classes of adaptivity with the total range from 17 to 204.

FLEX LIGHT 2.0				WEIGHTING	ASSESSMENT VALUE				SCORE
LAYER	SUBLAYER	Nr.	FLEXIBILITY PERFORMANCE INDICATOR		Bad	Normal	Better	Best	
1. SITE/LOCATION		01(2)	Surplus of site space	1			3		3
2. STRUCTURE	2.1 Measurements	02(5)	Surplus of building space / floor space	2		2			4
		03(11)	Surplus free of floor height	3				4	12
	2.2 Access	04(17)	Access to building: location of stairs, elevators, core	2	1				2
	2.3 Construction	05(21)	Surplus of load bearing capacity of floors	3			3		9
		06(29)	Extendible building / unit horizontal	3		2			6
		07(30)	Extendible building / unit vertical	1	1				2
3. SKIN	3.1 Facade	08(42)	Dismountable facade	3				4	12
4. FACILITIES	4.1 Measurement & control	09(53)	Customisability and controllability of facilities	2	1				2
	4.2 Dimensions	10(56)	Surplus facilities shafts and ducts	2	1				2
		11(57)	Surplus capacity of facilities	3	1				3
		12(65)	Disconnection of facilities components	2			3		6
5. SPACE PLAN/FINISHING	5.1 Functional	13(70)	Distinction between support - infill (fit-out)	3		2			6
	5.2 Access	14(73)	Access to building: horizontal routing, corridors, gallery	1		2			2
	5.3 Technical	15(77)	Removable, relocatable units in building	3	1				3
		16(78)	Removable, relocatable interior walls in building	3			3		9
		17(79)	Disconnecting/detailed connection interior walls; hor/vert.	3				4	12

Total Adaptivity Score: 95

Adaptivity Class: 3

CLASS TABLE Adaptivity Scores	Score Range
Class 1: Not adaptive	17 - 54
Class 2: Hardly adaptive	55 - 92
Class 3: Limited adaptive	93 - 130
Class 4: Good adaptive	131 - 168
Class 5: Excellent adaptive	169 - 204

Figure 2: FLEX 2.0 LIGHT, a practical and easy to use light version of the assessment method with a limited number (17) of the most important indicators (Geraedts 2015)

In the example of figure 2 the total Adaptivity Score is 95. When looking up this score in the class table, the related Class = 3: the building is Limited Adaptive.

2.3 Matching Demand and Supply: Gap Analysis

With the instrument FLEX 2.0 LIGHT as described in paragraph 2.2 four assessment levels of the different flexibility indicators are possible from 1 = Bad to 4 = Best (see figure 3).

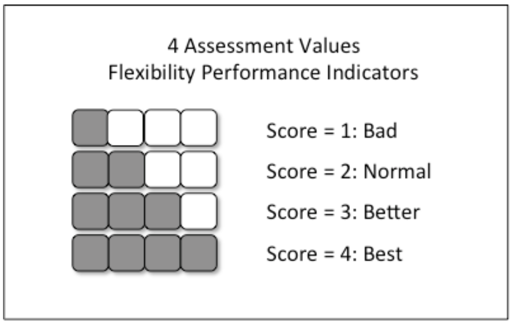

Figure 3: Visual representation of the four possible assessment values of the flexibility indicators, from 1 = Bad to 4 = Best (Geraedts 2014)

A very important aspect of this method is that owners and users of buildings can formulate a flexibility demand profile based on the chosen assessment flexibility indicators and compare this with the supplied building flexibility profile (see figure 4).

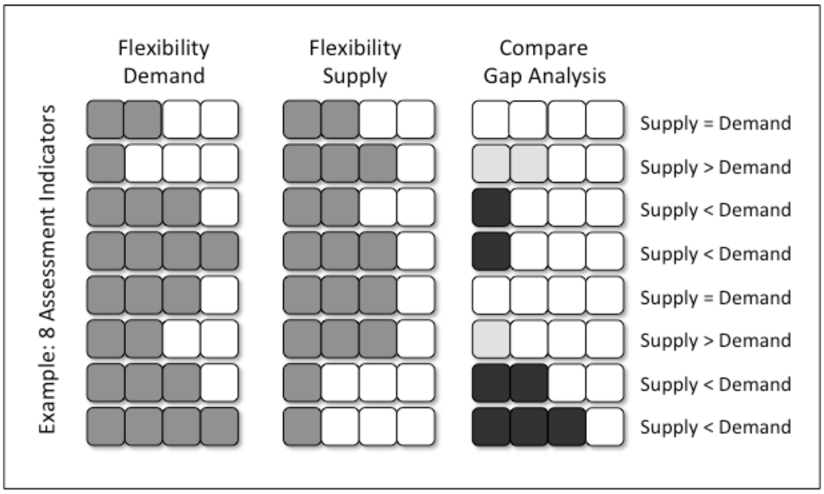

Figure 4: The comparison (gap analysis) between the demand for flexibility and the supplied flexibility in a building; in this example based on 8 flexibility indicators (Geraedts 2014)

3. Evaluation by Research in Practice

At the same time when FLEX 2.0 LIGHT was developed, the more extensive method FLEX 2.0 with 83 flexibility indicators was used in two separate research projects for an evaluation with specific experts in practice. One research project concerned the development of (high) school buildings (Carlebur 2015); the other project was related to the development of office buildings (Stoop 2015). The results of these research projects are briefly presented in the next paragraphs.

3.1 Adaptive School Buildings Determination Method

Methodology

The main research question in this school buildings project was as follows: which indicators determine the adaptive ability of educational real estate and how can these be implemented to create an assessment method which can review the current real estate, and can also be used as a standard for formulating the program of requirements? In order to answer these research questions three research methods were used: a literature review, a panel survey and a Delphi research. A panel of 30 professionals working in the educational sector contributed in this survey. The panel consisted of both users and owners and also experts from the developmental sector. The survey used 83 adaptivity indicators from FLEX 2.0 and the experts reviewed the indicators on their importance for adaptive building in the educational sector (Carlebur 2015).

Results

The experts of the educational sector selected 21 of the most important flexibility performance indicators. They also ranked the indicators based on their importance for increasing the adaptivity of the educational real estate (high school level). Figure 5 shows an example of a fictive assessment of a certain high school building. Each of the 21 indicators has been given a weight relative to the other indicators (weighting 4 - 1). Also each indicator is assessed (assessment value 1 - 4). This leads to a score per indicator and summed up to a total Adaptivity Score (121 in the example). At the same way a theoretical minimum score can be found of 55 and a maximum score of 220. Within these two borders a class table can be made with four different classes of adaptivity (see figure 5). When looking up this score in the class table, the related Class = 2: the school building is Hardly Adaptive.

EDUCATIONAL REAL ESTATE			WEIGHTING	ASSESSMENT VALUE				SCORE
LAYER		FLEXIBILITY PERFORMANCE INDICATOR		Bad	Normal	Better	Best	
CONSTRUCTION	1	Positioning obstacles / columns in load bearing structure	4	1				4
	2	Extendible building / unit horizontal	4				4	16
	3	Extendible building / unit vertical	4		2			8
	4	Rejectable part of building / unit horizontal	4			3		12
	5	Access to building; location of stairs, elevators	4				4	16
	6	Surplus of building space / floor space	3	1				3
	7	Surplus free floor height	3		2			6
	8	Measurement system; modular coordination	3	1				3
FACILITIES	9	Overdesign/surplus of facilities (E, H, ICT)	4			3		12
	10	Modularity of facilities	3		2			6
	11	Customisability and controllability of facilities	3	1				3
	12	Disconnectability of facilities components	1		2			2
SKIN	13	Day light facilities	2				4	8
	14	Location and shape of daylight facilities	2		2			4
	15	Facade windows to be opened	1				4	4
SPACE PLAN	16	Distinction between support - infill/fit-out	3	1				3
	17	Removable, relocatable interior walls in building	2		2			4
	18	Disconnecting/detailed connection interior walls; hor./vert.	2	1				2
	19	Multifunctional building	1			3		3
	20	Horizontal routing, corridors, access	1	1				1

							Total Adaptivity Score:	121
							Adaptivity Class:	2

CLASS TABLE EDUCATIONAL REAL ESTATE Adaptivity Scores	Score Range
Class 1: Weak. Not adaptive	55 - 92
Class 2: Moderate. Hardly adaptive	93 - 132
Class 3: Acceptable. Limited adaptive	133 - 172
Class 4: Good adaptive	173 - 220

Figure 5: Example of the fictive assessment of a certain school building, the total Adaptivity Score (121) and the Adaptability Class (2) of the school concerned (Carlebur 2015)

3.2 Adaptive Office Buildings Determination Method

Methodology

This research by Stoop was founded on two perspectives: on the one hand the current context of the office market (vacancy) and on the other hand the absence of a practical and manageable measuring instrument to assess the adaptive capacity of office buildings. The goal of this research project was to elaborate the method from FLEX 2.0 into a manageable version for the office sector with the focus on two research questions: which indicators of the FLEX 2.0 method characterise the adaptive capacity of office buildings? What does an instrument that measures the future value of office buildings based on these indicators look like? To answer these questions, different research methods have been used: a literature study, interviews with experts from practice and a test in two pilot cases.

OFFICE BUILDINGS			SPECIFIC PRIORITY	
LAYER	NR	FLEXIBILITY PERFORMANCE INDICATOR	TRANS	USE
SITE/LOCATION	1	Multifunctional location	x	x
	2	Expandable location	x	
STRUCTURE	3	Building entrance, location of elevators, stairs, cores	x	x
	4	Positioning pipes and shafts	x	x
	5	Storey height	x	x
	6	Insulation between stories and units	x	x
	7	Bearing capacity of floors	x	
	8	Column layout	x	x
	9	Positioning obstacles supporting structure	x	x
	10	Availability of stairs and elevators	x	x
	11	Expanding / reusing stairs and elevators	x	x
	12	Division support - infill		x
	13	Fire resistance supporing structure	x	
	14	Oversized building space/surface	x	
	15	Available floor area	x	x
	16	Size of storey		x

	26	Independance user units		x
	27	Adjustable and controlable installations		x
	28	Distribution / modularity installations	x	x
	29	Distribution heating and cooling installations		x
	30	Dismountable facility components	x	x
SPACE PLAN	31	Accessible facility components	x	x
	32	Horizontal routing, corridors, units	x	x
	33	Detailing joints inner walls - horizontal/vertical		x
	34	Possibility suspended ceiling		x
	35	Possibility elevated floor		x

Figure 6: The 35 most important flexibility indicators for office buildings (Stoop 2015)

Results

In figure 6 the presented indicators characterise the adaptive capacity of office buildings. The first column represents the layers that cluster the indicators. According to Brand these layers distinguish themselves by different life spans (Brand 1994). The second column shows the 35 most important indicators of the adaptive capacity of office buildings. The next two columns address the specific priority of that indicator: Transformation Dynamics (the capacity of a building to react to a change demand of the building function) or Use Dynamics (the capacity to react to a change in user demands). In contrast to FLEX 2.0 LIGHT and a similar instrument for educational real estate as described in paragraph 3.1, the instrument for office buildings does not use a weighting factor between the different flexibility indicators, nor calculates a final flexibility score.

4. Next generation: a new framework for FLEX 3.0

At this moment three different instruments are more or less derived from FLEX 2.0 (the one with the original 83 flexibility performance indicators). In figure 7 these three instruments are presented and combined with each other:

1. FLEX 2.0 LIGHT with 17 indicators and generally applicable (Geraedts 2015),
2. An Assessment instrument for school buildings with 21 indicators (Carlebur 2015),
3. An Assessment instrument for office buildings with 35 indicators (Stoop 2015).

				17	21	35	44	32	

Figure 7: FLEX 3.0, the integral combination of the three developed instruments to assess the adaptive capacity of buildings with 44 flexibility performance indicators in total

Next to the 'Instrument' column the 'Dynamics' column is shown. The 'T' stands for Transformation Dynamics, the capacity of a building to react to a changed market demand of the building function from an owner's point of view. The 'U' stands for Use Dynamics, the capacity of a building to react to a changed user demands from a users point of view.
This new FLEX 3.0 framework has in total 44 flexibility performance indicators that are all applicable for assessing the transformation dynamics while 32 of them are also suited for assessing the user dynamics of a building. Figure 7 also shows the seven general applicable flexibility performance indicators (most right column). They can be used for each type of real estate. The other 37 more specific indicators can be used for the assessment of specific real estate like schools or office buildings.

4.1 Support - Infill theory for a generic assessment instrument

This paragraph formulates an additional point of view on the gained results so far for explaining the potential future development. Habraken developed in the sixties a theory to distinguish construction components by different life spans (long and short life cycles), by different decision levels (community or individual), by different building levels (urban tissue, support, infill), or by differences in dealing with components (fixed or variable components). This is also known as the so-called Support-Infill theory (Habraken 1972). Similar to this theory it could be possible to distinguish flexibility performance indicators that are general applicable (on 'support' level for each building type (the seven indicators in the most right column of figure 7) and the other 37 indicators (on 'infill' level) that are more specific for a special type of real estate; in this case school buildings or office buildings. Further research in the near future will be necessary to elaborate this theory further and to develop the next version of this flexibility assessment instrument to be very useful in practice (FLEX 3.0).

5. Conclusions

In 2014 report was given of an extensive international literature survey and the development of a method to determine the adaptive capacity of buildings (Geraedts 2014). In total 147 flexibility indicators were described with accompanying assessment values. The most important recommendation for the next step was the development of an easy to use assessment method in practice with a limited number of important adaptability performance indicators. Further research led in 2015 to a renewed assessment method with 83 indicators, clustered in five layers with different life cycles. This method was called FLEX 2.0 and a so-called FLEX 2.0 LIGHT derived version with only 17 of the most important indicators (Geraedts 2015). At the same time in two separate research projects this method was used for an evaluation with experts in practice. One research project concerns the development of school buildings (Carlebur 2015), the other project relates to the development of office buildings (Stoop 2015).
In this paper the three different instruments derived from FLEX 2.0 are described and combined with each other to model the frame for the next version of a general and easy to use instrument to formulate the demand for adaptability on the one hand and assess the supply of the adaptability of buildings on the other hand: FLEX 3.0.

One of the main conclusions of this research project is that real estate experts from practice found the developed methods very useful. Furthermore, more additional research is required to improve the concept. One very good applicable development will be based on Habrakens support and infill theory as explained in the conclusions before (Habraken 1972).

Also financial effects of the costs and benefits of flexibility measures will have to be subject of further research, especially to convince owners and developers of buildings. Some indicators probably require lower initial investments than others. The relation between the investments and the extent of adaptive capacity will have to be studied, with a better judgement about the financial consideration to invest in adaptive capacity as a result.

Finally the assessment values of the indicators were not taken into account in this research. It would be interesting to evaluate if the assessment values are still valid, or if they should be strengthened or expanded. Weighting factors could be linked to the assessment values. Then it would be possible to work towards a certification of adaptive capacity.

Abstract

The awareness of, and need for sustainable construction (SC) is relatively well acknowledged in the construction industry. However, like the concept of sustainable development, it is open to different definitions; the way it is implemented can also vary depending on the perspective adopted. In this paper, the term is used to refer to all decisions and actions during the design and construction of buildings, which are designed to ensure that both the process and outcomes of construction over the lifecycle of a building are sustainable. This paper reports on the preliminary findings of a survey that was conducted to investigate the nature and characteristics of SC with a view to developing an understanding of the potential risks and likely impacts of SC practices on building projects in the UK. The survey was targeted at clients and AEC professionals with information being collected on SC goals, strategies, tools, techniques, risks and benefits for particular projects respondents had worked on. Preliminary findings suggest that the key motivation for SC is to minimise lifecycle operational costs; key goals include the minimization of waste, and ensuring that energy costs are below average. High capital cost was seen as the key risk; the reduction of operations costs, improved marketing and health and productivity gains are perceived benefits. The findings also raise questions for further research, about the impact of project related factors on SC practices and the awareness of professionals of strategies used in a phase of a project that they're not involved in.

Keywords: AEC professionals, building projects, clients, sustainable construction

1. Introduction

The importance of sustainable development for the ongoing sustenance of life and the transformation of our world into a liveable place for all, is now widely acknowledged (WCED, 1987, UN, 2015). The attainment of "development that meets the needs of the present without compromising the ability of future generations to meet their own needs" (WCED, 1987:43) requires concerted efforts to devise policies and strategies, which have been the subject of many international initiatives. For example, the most recent Agenda for Sustainable Development, which supersedes the Millennium Development Goals has 17 Sustainable Development Goals (SDGs) and 169 targets in relation to people, planet, prosperity, peace, and partnership (UN, 2015). The achievement of these goals and targets requires the cooperation of many stakeholders and sectors to ensure that economic and social development are not achieved at the expense of the environment (Ofori, 2015).

In the construction industry, the consideration of sustainable development is usually within the context of sustainable construction, as the industry can be seen as both a contributor to sustainable development as well as a process that incorporates sustainability principles into its practices (Ding, 2005; Shelbourn et al. 2006; HMG, 2008; Halliday, 2008; Atkinson et al. 2009; Goh and Rowlinson, 2013). This paper reports on the findings of a scoping study, which was aimed at investigating the nature and characteristics of sustainable construction (SC) with a view to developing an understanding of the potential risks and likely impacts of SC practices on building projects. The concept of sustainable construction is explored in the next section, and thereafter the research undertaken and the findings from the survey are presented and discussed. The paper concludes with recommendations for further research.

2. Sustainable Construction

The construction industry has a direct impact on the built environment and plays a central role in promoting sustainability. Through its activities and outputs, it contributes to the economy, enhances the quality of life of society, and impacts the environment (HMG, 2008). In this paper, we define sustainable construction (SC) as: all decisions and actions during the design and construction of buildings, which are designed to ensure that both the process and outcomes of construction over the lifecycle of a building (or other built asset) are sustainable (economically, socially and environmentally). This is in recognition that the construction industry (otherwise referred to as the Architecture, Engineering and Construction (AEC) sector) is essentially project based, and mainly deals with the creation phase of built assets. But there is an acknowledgement that design and construction has lifecycle implications and are influenced by various stakeholders such as clients, governments and regulatory bodies and AEC professionals who use their knowledge, skills and expertise in translating client requirements into completed built assets.

Sustainable construction involves two interrelated dimensions: outcomes and process. These are reflected in the UK government strategy on SC as “ends” (with respect to mitigating environmental impacts and resource consumption) and “means” (with respect to innovative and improved practices and regulation that will ensure the desired outcomes) (HMG, 2008). Goh and Rowlinson (2013) identify nine principles of SC, which incorporate both process (e.g. design process, lifecycle costing) and outcomes (e.g. environmental impact, lifespan), although some principles (e.g. resources and materials consumption) can apply to both process and outcome. The sustainability issues identified by Atkinson et al (2009) also reflect a range of environmental impacts such as climate change, water resources, land take and remediation, etc.

Within the context of the short-term nature of construction projects (in comparison to the lifespan of assets), it is not easy to assess (long-term) outcomes at the immediate conclusion of a project, given rise to the traditional approach of considering time, cost and quality as key measures of project success (De Wit, 1998, Yu et al, 2005). It does suggest that while a good understanding of outcomes is necessary, there should be emphasis on the process to ensure that desired outcomes are achieved.

Against this background (e.g. of different stakeholder involvement in construction), and assuming that the concept of sustainable construction is now fairly well established, the research reported in this paper sought to gain insights into the realities of sustainable construction on building projects; drivers for, and strategies for its implementation in practice (e.g. what lifecycle issues/intended outcomes are incorporated in the design/construction stage); what, if any, are its risks and benefits; and whether there were any project related factors (e.g. type, contract value, duration, etc.) that influenced sustainable construction practices.

3. Research Methodology and Process

The research approach was exploratory in nature, aimed at soliciting views from various stakeholders that will later form the basis of more in-depth studies. It was therefore decided that a questionnaire survey was the most appropriate approach to collect such varied views.

The focus of the survey was on Building Projects in the UK, and it was administered through an online questionnaire developed with Survey Monkey. A pilot survey to test the construct validity of questions was run from October – November, 2012 and was circulated to architects, client representatives, project managers and facility managers (a total of 10 people). The responses to this pilot (70% response rate) was used to refine the final questionnaire. The link to the online questionnaire was circulated to a list of clients and AEC organisations compiled from the Association of Consultancy and Engineering (ACE) in the UK, Architectural firms and Construction Organisations (total of 200). It was also circulated to members of the Co-operative Network for Building Researchers (CNBR), an international email "list for those who have an interest in building research and related fields [academics and practitioners]" with 3858 members (https://groups.yahoo.com/neo/groups/cnbr-l/info), between December 2012 and February 2013.

The 23 questions in the questionnaire were divided into five (5) sections: Respondent Details and Experience (questions on professional background and number of years of experience of construction projects) Specific Project Information on a recent (within 5yrs) building project (e.g. type, sector, contract value; procurement, duration, location and main structural system); Project Sustainable Construction (SC) Goals and Strategies (ranking of SC goals, motivation, key driver(s) for SC project goals., key strategies adopted during design and construction, techniques and tools used to assess project sustainability); Risks and Benefits of SC (risks associated with SC, causes of risks, how risks were addressed during design and construction phases, expected benefits of SC); and Free text comments on SC strategies and implementation on reported project, SC policies and practices in the UK. Respondents were given the option to provide their contact details if they wanted to receive an electronic copy of the survey summary. All those who provided this information were sent a summary of the findings.

4. Survey Results and Data Analysis

The data was analysed using IBM SPSS Statistics version 22 (IBM, 2013). There were 48 responses (on 48 projects) representing a response rate of 24% (using the list of 200, as it was not possible to determine the proportion of CNBR members who could have completed the questionnaire). However, not all respondents completed every question in the questionnaire, and the findings for each question presented below are for actual responses to each question.

4.1 Respondent Profile and Experience

Figure 1 shows the profile and experience of the respondents (43 and 42, respectively) who answered these questions. The majority of respondents were project/construction managers [25.6% (11)], architects [23.3% (10)] and civil/structural engineers [18.6% (8)]. The rest were: building services (mechanical and electrical) engineers, quantity surveyors/cost consultants, client representatives and a building surveyor. Regarding experience of the construction industry, 40.5% (17) had worked in the construction industry for more than 15 years; 9.5% (4) for between 11 -15years, 16.7% (7) for between 6 and 10years, and 33.3% (14) for 5 years or less.

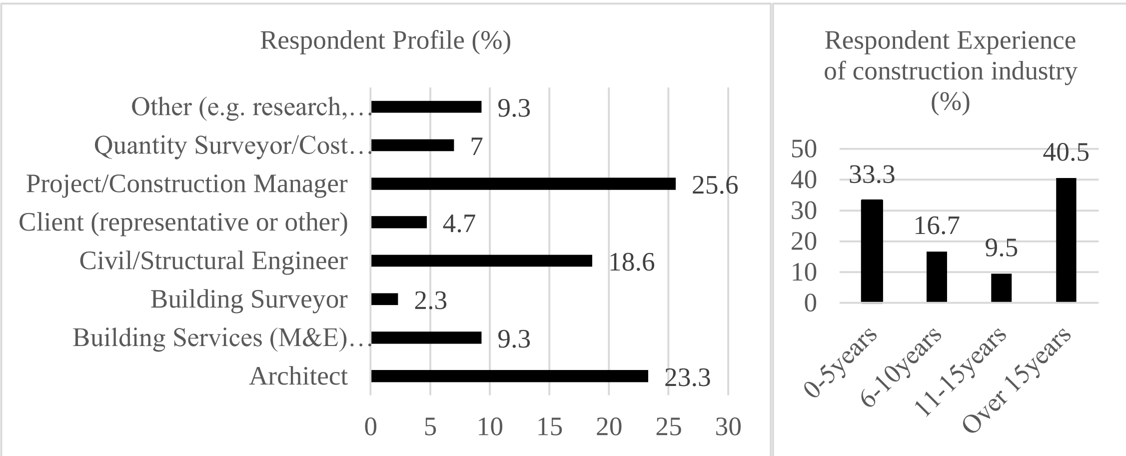

Figure 1: Respondent profile and experience

4.2 Project specific information

Responses for project specific information are summarised in Table 1 and includes information on: project type [majority, 81.2% being new build]; client sector [mostly commercial (37.5%), public sector (37.5%) and residential (21.9%)]; contract value [fairly spread across all categories, with the majority being under £500k (27.3%) and between £5-£10m (21.2%)]; procurement type [majority being procured through traditional contracts (53.3%), followed by design and build (23.3%)]; project duration (construction phase) [majority between 12-36months, followed by those lasting 12 months or less (23.3%)]; and main structural system [with the majority being reinforced concrete framed structures (44.4%), followed by steel-framed buildings (33.3%)]

Table 1: Project specific information

Question	Project specific information	Frequency	Percent (%)	N (%)	Missing (%)
Project Type	New Build	26	81.2	32 (66.7)	16 (33.3)
	Refurbishment	6	18.8		
Client Sector	Commercial	12	37.5	32 (66.7)	16 (33.3)
	Residential	7	21.9		
	Public Sector	12	37.5		
	Other (Education)	1	3.1		
Contract value	0-£500k	9	27.3	33 (68.8)	15 (31.3%)
	£500k-£1m	5	15.2		
	£1m-£5m	6	18.2		
	£5m-£10m	7	21.2		
	Over £10m	6	18.2		
Procurement Type	Traditional Contracting	16	53.3	30 (62.5)	18 (37.5)
	Design and Build	7	23.3		
	Construction Management	2	6.7		
	Management Contracting	2	6.7		
	Private Finance Initiative	3	10.0		
Duration (construction phase)	0-12monts	7	23.3	30 (62.5)	18 (37.5)
	12-36months	20	66.7		
	36-60monhs	1	3.3		
	Over 60months	2	6.7		
Main Structural System	Steel Framed	9	33.3	27 (56.3)	21 (43.8)
	Reinforced Concrete Framed	12	44.4		
	Timber Framed	1	3.7		
	Load Bearing Bricks/Blocks	4	14.8		
	Other (precast)	1	3.7		

4.3 Project sustainable construction goals

The sustainable construction goals that were adopted for the projects reported on were: *minimising waste (e.g. of water, materials, etc.) during construction* (10/11 projects – 90.9%); *ensuring that energy costs are below average for that type of building* where (9/11 projects – 81.8%); *achieving economic regeneration of the area* (11/14 projects – 78.6%); *achieving above-average BREEAM rating* (9/12 projects – 75%). Regarding the motivation behind the sustainability goals, those that were relevant to the reported projects were: *to minimise lifecycle operational costs* (90.9% of responses); *to comply with organisational policy* (e.g. corporate social responsibility) (81.8% of responses); *to comply with government policy (obtaining statutory approval)* (72.7%); to create an exciting building (72.7%); and *to comply with government policy to obtain project funding* (63.6%). Of these reasons, the top two (minimising lifecycle costs and complying with organisational policy) were rated as of high or medium importance by 100% and 88.9% of respondents, respectively. The desire to create an exciting building was rated as of high or medium importance by 90% of respondents to the question. With regards to the drivers for sustainability, the responses showed that clients were the main drivers (10 out of 11, 90.9%) followed by designers and contractors (5 out of 11, 45.5% each), government (4 out of 11, 36.4%), and engineers (3 out of 11, 27.3%). An analysis of sustainable construction goals and project specific factors (Table 2) to see if there was any correlation between the two, showed that there was no association between SC goals and project specific factors.

Table 2: Comparison between SC goals and project specific information

SC Goals and Strategies	Chi-Square /P value	Project Specific Information					
		Project type	Client sector	Contract value	Procurement method	Duration (constr. phase)	Main structural system
Achieving economic regeneration of the area	Chi-Square	0.14	0.99	3.42	1.17	1.73	4.55
	P value	0.71	0.65	0.49	1.00	0.42	0.60
Achieving above-average BREEAM rating	Chi-Square	0.00	0.44	2.26	4.28	0.54	5.40
	P value	1.00	0.51	0.52	0.13	0.76	0.51
Achieving between 0 and 10% carbon emissions	Chi-Square	0.12	0.07	4.53	6.80	3.11	3.33
	P value	0.73	0.80	0.54	0.07	0.46	1.00
Ensuring that up to 20% of energy used in the building is from a renewable source (e.g. wind, solar)	Chi-Square	0.00	1.33	1.45	2.73	2.04	4.95
	P value	1.00	0.25	0.69	0.44	1.00	0.48
Ensuring that energy costs are below average for that type of building	Chi-Square	0.64	0.02	2.93	0.58	0.54	2.04
	P value	0.43	0.99	0.55	1.00	1.00	1.00
Minimising waste (e.g. of water, materials, etc.) during construction	Chi-Square	3.93	1.52	1.32	1.32	0.24	0.92
	P value	0.09	0.25	1.00	1.00	1.00	1.00
There were no clear goals	Chi-Square	0.28	0.74	1.67	1.67	0.28	1.11
	P value	0.60	0.39	1.00	1.00	1.00	1.00

4.4 Sustainable construction strategies in design and construction

Key strategies for SC during design are shown in Table 3. Those adopted on the majority of the 11 projects reported were: *specifying A-rated materials (as per the Green Guide to Specification* – (Anderson et al. 2009)*)* (90.9%)*; building envelope insulation technology* (90.9%); use of *heat recovery systems* (72.7%) and *rainwater harvesting* (54.5%). The relative importance of these strategies (on 10 projects) showed that: *building envelope insulation technology* was of high importance in 7 (70%) projects and of medium importance in 3 (30%) projects; *specifying A-rated materials* was of high importance in 5 projects (50%) and of medium importance in 5 (50%) of projects. This suggests that *building envelope insulation technology* was the top strategy adopted at the design stage to achieve SC goals.

During construction the strategies that were adopted on the majority of the 11 projects for which information was provided were: *applying water saving methods to construction* (90.9%); *off-site prefabrication* (81.8%); *delivery of waste materials to recycling sites for re-manufacture* (81.8%); and *reuse of construction waste (or demolition) materials on the construction site* (80%). The relative importance of these strategies on 10 projects showed a mixed picture: *applying water saving methods to construction* was of high importance in 20% of projects, and of medium importance in 80%. For *off-site prefabrication* it was of high importance in 60%, medium importance in (20%) and low importance in 20%). For *delivery of waste materials to recycling sites* the corresponding figures were 30% (high importance), 60%, (medium importance) and 10% (low importance). For *reuse of construction waste* (9 responses), the relative importance was 22% (high), 56% (medium) and 22% (low). This suggests that while various strategies were adopted during construction, these were not necessarily of high importance in achieving SC goals.

Table 3: Key strategies adopted during design to achieve sustainability goals

Key Strategies adopted during Design to achieve Sustainable Goal for this Project	Relevant to this project	Frequency (Count)	Percent (%)	N (%)	Missing (%)
Rainwater or Greywater harvesting	Yes	6	54.5	11 (22.9)	37 (77.1)
	No	5	45.5		
Heat recovery systems (e.g. CHP systems)	Yes	8	72.7	11 (22.9)	37 (77.1)
	No	3	27.3		
Specifying A-rated materials (as per the Green Guide to Specification)	Yes	10	90.9	11 (22.9)	37 (77.1)
	No	1	9.1		
Passive Solar heating	Yes	3	27.3	11 (22.9)	37 (77.1)
	No	8	72.7		
Use of Photovoltaic panels	Yes	4	36.4	11 (22.9)	37 (77.1)
	No	7	63.6		
Building envelope insulation technology	Yes	10	90.9	11 (22.9)	37 (77.1)
	No	1	9.1		

4.5 Techniques and tools for sustainable construction

The techniques/tools used to assess SC issues are shown on Table 4. Those used on the projects reported (between 8 and 11) were: *BREEAM - BRE Environmental Assessment Method* (9/11 projects); *WLCC - Whole Lifecycle Costing* (8/10 projects); *Green Guide to Specification* (7/9 projects); *RSM Responsible Sourcing of Construction Materials* (5/8 projects); *DQI – Design Quality Indicator* (5/9 projects) and *CSH - Code for Sustainable Homes* (1/9 projects). Regarding the relative importance of these techniques, *BREEAM* was of high importance in 8 (72.7%) projects, of medium importance in 2 (18.2%) projects and low importance in 1 (9.1%) project. For *WLCC*, it was of high importance in 7 (77.8%) projects, medium importance in 1 (11.1%) project and no importance in 1 (11.1) project. For *Green Guide*, it was of high importance in 6 out 8 projects (75%), medium importance in 1 (12.5%) project and of no importance in 1 (12.5%) project. The rating for RSM was, 42.9% (high), 28.6% (medium), 14.3% (low) and 14.3% (no importance); for DQI it was: 42.9% (high), 28.6% (medium) and 28.6% (no importance); and for CSH, it was: 14.3% (high), 14.3% (medium); and 71.4% (no importance).

Table 4: Techniques or tools used to assess sustainable issues for projects

Techniques or Tools used to assess Sustainable issues for this Project	Relevant to this project	Frequency (Count)	Percent (%)	N (%)	Missing (%)
BREEAM - BRE Environmental Assessment Method	Yes	9	81.8	11 (22.9)	37 (77.1)
	No	2	18.2		
CSH - Code for Sustainable Homes	Yes	1	11.1	9 (18.8)	39 (81.2)
	No	8	88.9		
DQI - Design Quality Indicator	Yes	5	55.6	9 (18.8)	39 (81.2)
	No	4	44.4		
The Green Guide to Specification	Yes	7	77.8	9 (18.8)	39 (81.2)
	No	2	22.2		
RSM - Responsible Sourcing of Construction Materials	Yes	5	62.5	8 (16.7)	40 (83.3)
	No	3	37.5		
WLCC - Whole Lifecycle Costing	Yes	8	80.0	10 (20.8)	38 (79.2)
	No	2	20.0		

4.6 Risks and benefits in adopting SC strategies

The risks associated with the adoption of sustainable construction strategies on the 8 projects reported on were: *financial risk* (87.5%), *delays to design schedule* (62.5%), *complexity of construction* (50%), *delays to construction schedule* (50%). Regarding the relative importance of these risks, *financial risk* was of high importance on 6/7 projects (85.7%) and medium importance on 1/7 (14.3%) project. For *delays to design schedule*, it was of high importance on 3/7 (42.9%) projects, medium importance on 2/7 (28.6%) projects and low importance on 2/7 (28.6%)

projects. For *delays to construction schedule* (although not a risk on half of projects reported), it was of high importance on 4/6 (66.7%) projects and low importance on 2/6 (33.3%) of projects. The relative importance of *complexity of construction* was: 3/6 (50%) high importance, 1/6 (16.7%) medium importance, and 2/6 (33.3%) low importance. The biggest cause of risks associated with the adoption of SC strategies was: *high initial cost* (7/8 projects – 85%). The other options to this question (*immature technology*, *lack of skilled staff*, and *immature market*) did not receive meaningful responses.

The top expected benefits from the adoption of SC on the reported projects were: *reduce operational costs* (8/8 projects – 100%); *marketing benefit* (6/7 projects – 85.7%), *health and productivity gains* (6/7 projects – 85.7%); and *new business opportunities* (5/6 projects – 83.3%) All 8 projects indicated that *reduce operational costs* was of high importance. For *marketing benefit* and *health and productivity gains*, only 66.7% and 60% respectively said they were of high importance. For *new business opportunity*, only 40% said it was of high importance.

5. Discussion

The objective of the study reported in this paper was to gain insights into the actual implementation of SC (with respect to goals, strategies, techniques and risks/benefits) on building projects in the UK. Given that almost half of the respondents (48.9% - Fig 1) were professionals (architects and project/construction managers) who normally have an overview of the entire project process (especially for traditionally procured projects), and that two-thirds of them (66.7%) had over 5 years of experience of the construction industry, it is expected that their responses reflected a good knowledge of the industry and of project activities. The predominance of traditional procurement in the projects reported on (Table 1) is also fairly comparable with the findings of a national (UK) survey of construction contracts around the time of the survey (NBS, 2012), which suggest that the findings are based on projects that are fairly representative of projects nationally (at least in procurement type). It is however disappointing that there were poor responses to key questions on sustainable construction goals, strategies, etc. This might have been due to a lack of time to complete all questions, or that respondents simply didn’t know the answers, or indeed that there were no clear SC goals or strategies for those projects. If it was due to ignorance on the part of respondents, it raises questions about the awareness of SC goals and strategies by all participants on a project, or whether indeed these are made clear in project documentation. It might also suggest (as commented by a respondent in the free-text section of the questionnaire) that SC practices are “generally fragmented.” If the missing information was because there were no SC goals for those projects then it raises questions on the extent to which SC is being considered on projects.

The poor responses to key questions undermined any detailed analysis of the relationships between project-related factors and the goals, strategies, techniques, risks and benefits of sustainable construction (as was attempted in Table 2). But there are some interesting insights from the findings. For example, the SC goals that were relevant to reported projects (section 4.3) reflect both the ‘process’ (e.g. minimising waste during construction) and the ‘outcomes’ (e.g. relatively low energy costs) aspects of SC (HMG, 2008), and largely the economic (achieving economic regeneration) and environmental (energy use, high BREEAM rating) aspects of sustainability (economic regeneration can also have social benefits). The motivation behind these goals (e.g. to minimise lifecycle operational costs) suggest an appreciation of lifecycle issues. It is also encouraging that the SC agendas on these projects were mostly driven by clients and their policy for corporate social responsibility (section 4.3). This suggests a more positive view of SC and not just a desire to comply with regulatory requirements for statutory approvals or project funding. It would also appear from the free-text comments of one respondent, that some organisations have developed (and are developing) pioneering policies, "which provide stringent requirements on regeneration, environmental sustainability, health and [wellbeing]"

The relevant strategies for SC during design and construction are to be expected (respondents did not provide additional options to the coded answers given in the questionnaire) but it is interesting to see that during design, the emphasis appears to be more with "outcomes" aspects of SC (lifecycle performance of materials, insulation, energy efficiency), whilst construction appears to focus on waste minimisation, mainly a "process" issue, but with economic and long-term environmental impact considerations. Reported SC design strategies did not appear to be explicitly geared towards the facilitation of SC strategies at the construction stage (probably because of how the questionnaire was framed), but this can be explored in future research.

Regarding risks and benefits, it is not surprising that financial risk (e.g. high initial cost, which is also mentioned in the free text comments of one respondent) and reduction of operational costs were the top risk and benefits, respectively, on most projects reported. Both reflect some form of financial cost or reward and might suggest that financial costs/benefits have a key underlying motivation for SC (this is supported by the declared motivations for SC, and SC strategies at the construction stage). On the other hand, immature technology, lack of skilled staff and immature market, were not considered as causes for SC risks. Does this mean that appropriate technologies and personnel are available to implement SC practices? The evidence from this study might suggest so, but further studies are required to generalise this to the wider construction sector.

6. Conclusions

This paper has presented the preliminary findings of a survey into SC practices on building projects in the UK. The aim was to gain insights in the actual implementation of SC and to explore whether there are any relationships between SC goals, strategies, techniques, risks, benefits and project specific factors. The relatively low responses to vital questions did not allow detailed analysis to explore these relationships. The findings can only be applied to the reported projects as there were insufficient responses to make generalisations to the wider construction sector. Another limitation is that the survey was conducted a few years ago and SC and other project practices might have changed over this period (e.g. a more recent survey of construction contracts in the UK showed that design and build procurement is almost as popular as traditional procurement – NBS (2015) – a different profile from the survey in 2012 (NBS, 2012)). However, the study does provide useful insights and raises questions for further research.

Key findings include the fact that current (at the time of the survey) practice with respect to goals and strategies fairly reflected the understanding of SC in terms of “ends” and “means” (HMG, 2008) although social aspects of sustainability were not reflected as much as economic and environmental factors. The findings also suggest a more positive attitude towards sustainable construction which is not just about compliance with regulations (‘box-ticking exercise). There appears to be however, a strong financial motivation for SC, suggesting that a strong financial case for SC might well encourage more SC practices.

Questions arising from the findings include: the level of awareness of SC goals and strategies by all stakeholders in a project (a subject explored by Rafindada et al. 2014 in their paper on sustainable construction project risks), the extent to which SC strategies are integrated across the project process (e.g. how SC design strategies feed into SC construction strategies), and whether indeed SC practices are widely implemented on building projects in the UK

Next Generation Healthcare Buildings in South Africa: Complexities and Opportunities for Sustainability

Peta de Jager, Theunis Knoetze, and Geoff Abbott

CSIR Built Environment, CSIR South Africa
Email: pdejager@csir.co.za

Abstract

Hospitals are widely recognised to have complex design and engineering requirements. It might be argued that the unique functional constraints and operational demand placed upon the hospital building may counter sustainability imperatives. Yet it stands to reason that, even with this complex building type, there must be opportunity to reduce embodied energy, operational energy consumption, to manage water and waste, and to promote social cohesion without compromising the desired safe, effective, efficient healing environment.

In South Africa there has been a commitment to transform the healthcare sector through the introduction of National Health Insurance which is to unfold over a 14 year period from 2011. While this is primarily a funding mechanism, it seems inevitable that over time the principles of universal coverage, eradication of inequity, and accessibility will be reflected in the architecture provided to support service delivery.

In preparation for the National Health Insurance the South African government has increased spending on healthcare infrastructure and initiated several support projects to strengthen quality and accelerate delivery of capital projects. This includes the development of a comprehensive set of new national norms, standards and benchmarks for healthcare building. South Africa has adopted a contextual approach to determining its new guidelines, norms and standards. Key concepts which have a bearing on sustainability are discussed in relation to constraints and opportunities.

The next generation of healthcare buildings in South Africa has created an opportunity to embed principles of environmental consciousness and sustainability into the policies and practices of built environment professionals in the healthcare sector.

Keywords: Sustainability, healthcare, buildings, guidelines, developing country

1. Introduction

Health outcomes and healthcare service delivery is profoundly affected by the built infrastructure provided to support it. The South African (SA) Constitution confers rights to all citizens of access to health services and to an environment which is not harmful to their health or well-being. This underpins an imperative for health planners and built environment professionals to be vigilant in planning, providing and operating healthcare infrastructure. There is significant work to be done in SA, if it is accepted that it is currently not on a sustainable trajectory, which the 2012 UNU-IHDP and UNEP report contends (p 272). According to the report this is - in large part - due to poor health status and poor life expectancy. The dual epidemics of tuberculosis (TB) and HIV/Aids resulted in a life expectancy dropping from 67 years in 1998 to around 57 years in 2012. Unemployment is estimated to be 27% and climate change is likely to lead to increasing water stress, reduced food security and loss of species and ecosystems (UNU-IHDP et al, p 272). Sustainability is about a balance between economic, environmental and social dimensions.

In SA there has been a commitment to transform the healthcare sector through the introduction of the national health insurance (NHI) system which is to be unfolded over a 14 year period commencing in 2011 (National Department of Health [NDoH], 2011). Whilst ostensibly and primarily conceived as a funding mechanism, it is inevitable that over time the NHI guiding principles of universal coverage, eradication of inequity, and accessibility to services (NDoH, 2011, pp 16 – 19) will be reflected in the built environment. In preparation for NHI the SA government has increased spending on healthcare infrastructure and the NDoH has initiated several support projects to strengthen quality and accelerate delivery of capital projects (2012). This includes the development of a comprehensive suite of new national norms and standards for healthcare buildings (N&S), with the stated objective of providing a "sustainable set for all levels of health care facilities to inform and guide work related to all stages of the life-cycle from strategic planning through to operation and disposal" (Infrastructure Unit Support Systems [IUSS], 2014).

Although SA climate change mitigation commitments, legislation and policy now make it obligatory for built environment projects to address sustainability, there is currently limited guidance on how sustainable development can be integrated in built environment projects. There is also the perception that addressing sustainability in buildings will be expensive and complicated, and that there are a range of competing social, economic and environmental priorities. Hospital infrastructure is widely recognised to have complex design and engineering requirements even without the additional dimensions of environmental, social and economic sustainability. It might then be argued that the unique functional constraints and operational demands placed upon the hospital building as a type may trump greening imperatives, invoking "defensible exemptions".

2. Objectives

The N&S is not intended to be applied in isolation, being required over and above a number of general legislative pieces and instruments. Of relevance to this paper this includes the SA

National Building Regulations (NBR)[1], the National Environmental Management Act (NEMA) and the Infrastructure Delivery Management System (IDMS)[2]. Nevertheless, development of the N&S provides an opportune moment to embed forward-thinking principles of environmental consciousness, as well as social as economic sustainability, into the policies and practices of built environment professionals in the next generation healthcare building.

3. Method

With reference to the current status, and a desired future healthcare estate, researchers discuss the anticipated contributions of N&S over and above the NBR, NEMA and IDMS to the sustainability agenda, as well as identifying "defensible exemptions" and possible shortcomings. The headings of the ten points articulated in the Vision of Sustainable Smart-eco Building in 2030 (henceforth "Ten Point Vision") by Chevalier et al was adopted as a broad framework to structure a qualitative analysis. This is discussed in the subsequent narrative.

4. Ten Point Vision

According to Chevalier et al, European standards and guidelines are inclined to approach the general principles of sustainability in a reductionist and fragmented fashion: Cited are the focus on progressive energy demand reduction and energy generation targets in new and existing buildings in Germany, France, and Italy. The authors posit that sustainable principles need to be SMART (specific goals that are strategic, measurable, assignable, realistic, and time-bound) (Doran, pp 35 – 36) on the one hand, and on the other hand progressive and ambitious. Chevalier et al propose a Ten Point Vision (2009) as a framework for sustainable smart-eco building. Although this is centred on the European context and for general building types over a twenty year horizon, it covers a range of issues, and has been selected by researchers of this paper as a suitable holistic generic framework.

The Ten Point Vision suggests sustainable smart eco-conscious buildings should:

- Apply the general principles of sustainability;
- Be designed or refurbished from a life-cycle perspective;
- Be designed or refurbished to be adaptable throughout the service life, with an end-of-life strategy;
- Have its environmental impact minimised over the estimated or remaining service life;
- Be healthy and comfortable for their occupants;
- Be established with consideration of their economic value over time;
- Have social and cultural value;
- Result from all interested parties' involvement and be designed or refurbished to meet the occupants' needs individually and collectively;
- Be completely integrated into a territorial strategy and accessible for all; and
- Be designed or refurbished to be user-friendly, simple and cheap to operate, with their technical and environmental performance measurable over time.

---

[1] Conforming to National Building Regulations is a newly emerging trend in public buildings in SA, many having been declared exempt until circa 2010.

[2] Can be accessed online from http://www.cidb.org.za/ , applicable to the public sector only

Each of these points is discussed systematically below as it pertains to the new draft N&S.

4.1 General principles of sustainability

The first point proposed in the Ten Point Vision is that buildings should conform to the Sustainability **in building construction -** General principles of as described in ISO 15392:2008. These principles are considered in relation to the N&S guidance in their entirety, and without regard for prioritisation and shown in Table 1

Table 1: General principles of sustainability

	Criteria /Achieved?	*Notes*
1	*Continual improvement* *Partial*	*A condition assessment method has been described. According to the published gazettes, compliance with N&S is mandatory, unless a motivated exemption is applied for and granted. This feedback mechanism could facilitate continual improvement of guidelines and by extension, buildings. However, minimal systematic updating has occurred to N&S since April 2014, limited to cost model tools which are updated quarterly for inflation and exchange rates and no means exists for systematically improving N&S.*
2	*Equity* *No/partial*	*The N&S were developed as a means of addressing inconsistencies in quality and expenditure in current capital work programs. As the application is only mandatory in the public sector its adoption will impact on new work in this sector, however is doubtful that will meaningfully impact most significant structural inequity (public vs. private disparity) and as it is not retrospectively applicable will only improve equity gradually (minimum 40 year replacement average).*
3	*Global thinking and local action* *Yes*	*The developers of the N&S have reviewed international literature and studied the Australasian Health Facilities Guidelines, British NHS Estates Standards, American Facility Guidelines Institute guides and concluded that these needed to be adapted to meet the specific opportunities and constraints of the local context. Some examples of SA context-specific considerations are with respect to preferential passive design response to climate opportunities, energy security, affordability constraints and airborne infection prevention and control.*
4	*Holistic approach* *Partial*	*The N&S address only conventional facility-based diagnostic and curative services, and do not address the health-promoting and preventive aspects of healthcare, nor alternative and traditional healthcare. To work toward overall building performance optimisation, interdisciplinary and novel approaches to design may be beneficial. N&S assume consultants retain conventional roles and responsibilities.*
5	*Involvement of interested parties* *Yes, limited to passive feedback*	*During the development phases of N&S, active involvement of identified experts and stakeholder representatives was encouraged through participation in a series of open workshops at which N&S development were discussed in themed sessions. These include participants with both clinical and built environment expertise. There is a dedicated project website which provides an open forum for sharing, dissemination and on-going stakeholder input allowing passive feedback. Involvement of interested parties could be strengthened and more actively pursued by making post-occupancy evaluation mandatory – not currently considered.*
6	*Long-term consideration*	*The N&S were drafted in a non-prescriptive way to allow for professional discretion and innovation. A future-healthcare environments workshop was held in order to anticipate future trends - such as telemedicine - which impact on healthcare infrastructure provision. However, current healthcare infrastructure planning is*

	Partial	*reactive and does not meaningfully take into account long-term dynamics in a structured way.*
7	*Precaution and risk* *Yes*	*The N&S provides guidance on mitigation through building design, material selection for several identified risks such as infection, slip, security (theft, vandalism), human error etc. (Worldwide healthcare associated infections and adverse events occur in 10% of admissions. Comparable studies are not available for SA, but could be expected to be at least in the same order of magnitude.) Precautionary measures for construction activities are discussed. General risk associated with construction, delivery etc. are described in complementary codes.*
8	*Responsibility* *(moral rather than legal/financial)* *No but described in IDMS and statutory councils*	*The public sector is characterised by a complex organisational design. Originating in the Constitution, each province enjoys relative autonomy. Infrastructure stewardship is conventionally split between the custodian (public works departments) and line departments (departments of health). Public works' core business is built environment-related but not necessarily versed in the specificities of healthcare requirements. Selection of built-environment professional consultants is usually based on a roster system. Without the prerequisite for prior experience (preferred by the private sector) there is a broader-based opportunity for participation in public-sector projects. This system does not, however, incentivise consultants to specialise in any public sector domain (including the health sector). User clients (i.e. facility-based health officials) are generally not repeat clients. Team member inexperience and a lack of formal guidance and regulation have led to extreme variation in form, quality, and cost of public healthcare infrastructure. N&S have limited guidance on roles, responsibilities and "rules of engagement". The conventions of practice are customary and described by the statutory professional councils (SACAP, ECSA, SAQSC) and through the IDMS process, however.*
9	*Transparency* *Yes*	*According to the Access to Information Act 2:2000, information related to public capital expenditure, healthcare infrastructure etc. should be available upon request. In practice this is rarely done, and this information is not readilly available. Auditing in the public sector ensures compliance with the Public Finance Management Act 1999. Limited private sector information is disclosed to maintain competitive advantage. However in the spirit of generosity and pursuit of improved healthcare infrastructure, the N&S development process inspired unprecedented cooperation and sharing of information.*

4.2 Life cycle perspective

The N&S includes documents on commissioning; decommissioning and maintenance address life-cycle stages beyond design, but are not explicitly geared for use in the design phases where pro-active measures should be introduced. The discipline of life-cycle analysis for construction materials and eco-labelling is in its infancy in SA and development of the N&S project has concluded without adequate reference to this discipline. Practical guidance on measuring or reducing embodied energy is not, for instance, addressed. The N&S cost model has been developed to take into consideration life-cycle costs. This takes into account that different building elements and materials have different expected service lives and in this way contribute to the quest for an affordable estate which does not solely focus on minimising initial capital costs. A decommissioning document forms part of the suite, but there is no guidance to identify or address end of service life and no mechanism to ensure implementation in practice.

4.3 Adaptable

The Ten Point Vision proposes that sustainable smart eco-conscious buildings should be designed or refurbished to be adaptable throughout the service life, with an end-of-life strategy. Typically hospitals and primary health care buildings are constructed using traditional brick and mortar generally resulting in fixed non-flexible structures. In an environment where technology dives rapid advancement in service delivery possibilities there is generally very limited flexibility built into health projects.

Given highly customised layouts of portions of hospitals (such as operating theatres) as well as the imperative to remain continuously operational, repurposing many components for other uses may be challenging: hospitals as currently constructed may not be good candidates for recycling and reuse. A flexible, adaptable open building systems approach may be appropriate in order to address the system uncertainties and complex specialised infrastructure requirements inherent in provision of healthcare. Open building systems may have the distinct advantage over conventional methodologies in healthcare settings of allowing building adaptation with minimal disruption to simultaneous service delivery or compromise to patient care. Yet services are conventionally provided from fixed, immovable structures which have lifespans of some decades. There is a document in the N&S suite for application of innovative building technologies - which may include open-building technologies - for clinics (i.e. small-scale). The number of larger scale healthcare buildings internationally adopting the open-building technology approach is limited with a few notable exceptions (INO Hospital, Bern, for example). In SA, migration to open building technologies would require non-trivial construction industry reskilling and building material supply transformation. Because of this, it is suggested that the requirement for adaptability be a defensible exemption for the health sector.

4.4 Minimising impact

The Ten Point Vision proposes that sustainable smart eco-conscious buildings should minimise their environmental impact over their estimated or remaining service life.

The National Environmental Management Act (NEMA) requires, inter alia, that building developers and owners must take reasonable measures to ensure that pollution or degradation of the environment is prevented or minimised in development and operation (NEMA Part 28). Local government has the authority to require an Environmental Impact Assessment and this prerogative is frequently exercised, more especially for green-field site development.

In support of the requirements contained in NEMA, the Environment and Sustainability document in the N&S suite (IUSS, 2014) provide a description of sustainable development and translates this into specific sustainable development objectives for the built environment and provides detailed checklists tailored specifically for healthcare infrastructure. These enable the setting of explicit and challenging targets to reduce operational energy consumption, manage water and waste for projects as well as systems to ensure that these are achieved, and provide a framework for self-assessment to ascertain the performance of projects in development and operation.

4.5 Health and comfort

The Ten Point Vision proposes that sustainable smart eco-conscious building should be healthy and comfortable for occupants. Patient and staff experience, healing environments, comfortable workplaces and prevention of healthcare associated infections and other adverse events are prioritised in the N&S.

In order to achieve indoor thermal comfort the Building Engineering Services N&S guide (IUSS, 2014) recommends that interventions should be considered, singly or in combination, in a hierarchy where passive and adaptive comfort systems are considered before fully mechanical systems. While there is a current paucity of detailed local climate data, the publication of local climate characterisation is expected shortly which will enable detailed evaluation of design response. TB, which is communicable exclusively through the air, is the leading cause of mortality in the region. It is recognised that building design and engineering has a role to play in mitigating risk as it impacts heavily on indoor air quality (World Health Organisation [WHO], 2009, CDC, 2005). Healthcare facilities inevitably bring susceptible and infectious individuals into close contact. According to Joshi et al (p 12) and Menzies et al (pp 593-605) and others, healthcare workers in middle and low income countries such as SA are at between four and 135 times more likely to contract TB compared to the background population. To address this major health risk, great care has been taken to describe design and engineering approaches to airborne infection that are locally-driven and are evidence based. The SA approach to building envelope design departs from one found in many European norms in that it does not generally promote hermetic sealing to reduce energy. Buildings are not typically heated or cooled for much of the year. Furthermore, perhaps in addition to considering comfort, sustainable building design could or should address well-being as criteria.

4.6 Economic value and affordability

According to the Ten Point Vision sustainable smart eco-conscious buildings should be established with consideration of its economic value over time.

Increasing expenditure to address the healthcare needs optimally rapidly raises challenges to affordability. There is abundant evidence that increasing expenditure on healthcare systems does not necessarily yield better outcomes (OECD). SA expenditure in health service provision (tracking the global trend) has risen steadily over recent years and there is international concern over the affordability (and hence sustainability) of this growth path. SA spends 8.3 % of its GDP on public and private sector health (The Presidency Republic of South Africa, 2011) and sectors compete for funding from a limited fiscus. An important challenge to the health system is capital, operational funding and staffing resource constraints. The whole healthcare enterprise must be carefully configured to ensure that operation of the full estate is affordable and sustainable. Integrated infrastructure planning which takes staffing, and operational resources which will be manifested over the building's projected life is required. To a limited extent, the N&S cost estimation tools can provide this by means of order of magnitude projections which include indicative operational cost forecasts for the medium term funding horizon enabling long term budget forecasting and reconciliation during planning.

Healthcare spending in SA is inequitably distributed across the public and private sectors. Treasury reports that 48.5 % of expenditure amounting to R120.8 billion is attributed to the private sector in the service of 8.2 million people (16.2 % of the population). Nearly half (49.2 %) of expenditure amounting to R122.4 billion is attributed to the public sector and is in the service of the remaining 42 million people (84 % of the population) (National Treasury, 2012). Although these figures are not directly comparable (the public sector figure excluding infrastructure provision) the contrast in expenditure has seriously undermined aspirations of equity, access to care and social justice. The N&S do not address both sectors and therefore will not have a direct role in resolving this economic value disparity.

4.7 Social and cultural value

In SA healthcare services enjoy great social and cultural value and its infrastructure can be symbolic of societal values of caring. This can be demonstrated in community response to opening and closure of such institutions. In SA there are historical and emergent social and cultural distortions which are expressed in the built environment. Healthcare infrastructure can be broadly characterised according to whether it is privately or publicly funded. This distinction can be linked – albeit with some limitations – (generalisation being crude) to broadly differing capital investment and building stock traits.

The private sector generally embeds lean systems thinking in its projects and values economic return on investment and organisational agility. There is recognition that healthcare built environments are necessarily substantively built-to-purpose, and specialist expertise to brief and designs is valued. The private sector invests in developing briefing and project implementation capacity in-house and cultivates relationships with experienced built-environment professional consultants for competitive limited repeat business. The project managers who implement private sector building projects have decision-making mandate to the extent that it satisfies corporate requirements. Limited experimentation is accepted but there is generally a conservative approach to building design and capital expenditure. The private sector replicates its successes with incremental refinements and adjustments over time. The larger hospital groups have become highly experienced, savvy clients. The private sector has dedicated legislation[3] which describes (amongst other things) some minimum space standards. There is general consensus that this legislation is outdated[4] although it is still in used to regulate some aspects of service provision (such as granting of licenses for hospital beds).

Formerly the public sector was regulated by the now repealed SA Hospital Norms (SAHNorms) with reference to maximum allowable areas and costs. In the absence of national public sector legislation, the public and media tend to benchmark private sector with the public sector, and conclude that the public sector is failing. The disparity in expenditure discussed above is sometimes acknowledged (National Treasury, p 8), but there is widespread despondency and

[3] The Regulation 158 (“the R158”) or Regulation187 in the Western Cape province
[4] last revised in 1993, in the pre-democratic era

lack of morale in the public sector despite significant successes and its crucial contribution to the uninsured majority.

4.8 Stakeholder involvement

Post-occupancy evaluations of three recently completed SA hospitals (van Reenen, unpublished) have found that there is no systematic involvement by communities in the design phase (although communities do get involved in ensuring local community employment in the facility when open and there is a structured national programme to involve local labour participation in the construction programme). There is only limited involvement of client department. For example, detailed mock-ups of rooms to convey actual size was not used as a technique

4.9 Territorial strategy

According to the Ten Point Vision sustainable smart eco-conscious buildings should be completely integrated into a territorial strategy and accessible for all. SA has a healthcare infrastructure platform which reflects the pre-democratic era: Gaps where the majority of population did not receive basic services; overlaps and duplicate services where apartheid structures were separately provided for different race groups; and private sector facilities which emerged in the 1980s, exploded post democracy to serve the insured population. The N&S guidance was originally envisaged to address all life-cycle stages but infrastructure strategic planning was removed from the scope of work. There is no evident coordinated geospatial planning programme and no [published/ discernible/ explicit] territorial strategy. Project, site and service selection does not appear to be systematically supported, except by exception, by study of accessibility and population and demand dynamics. Furthermore, leadership have expressed the perception that healthcare services may not be effectively delimited to nationals only (Lindeque, 2015). If true and unmanaged this could overburden constrained resources. Even if untrue, such perceptions may undermine social cohesion and lead to xenophobia and conflict. Given that the investment in infrastructure is on average a 40 year venture, with enormous concomitant capital, operational and human resource implications, it stands to reason that the absence of a territorial strategy is a credible concern to achieving a sustainable healthcare infrastructure platform.

4.10 User-friendliness

According to the Ten Point Vision sustainable smart eco-conscious buildings should be designed or refurbished to be user-friendly, simple and cheap to operate (i.e. maintainability), with its technical and environmental performances measurable over time. The N&S guidance[5] requires healthcare facility design to address user friendliness for occupants. In addition to the

[5] Ironically N&S guidance material itself is not adequately user-friendly. For convenience, and to satisfy the development time of three and a half years ab initio, the guidance was divided into 46 work-packages and each discreetly developed. This has resulted in unfortunate repetition and an unnecessary volume of material (in excess of half a million words). It is also not easy to locate or navigate in its current repository.

NBR requirements, it dictates that facilities are of inclusive design (wheelchair friendly, well-signposted, clearly laid out etc.) and in this way address user-friendliness. There is an explicit requirement to exhaust passive design technologies first, then hybrid systems and finally mechanical solutions to promote simple and cheap operation as well as to address energy insecurity.

There has been substantial, serious lack of maintenance of public healthcare facilities (with few exceptions) over a period of several years resulting in a general poor condition of infrastructure (SA Institution of Civil Engineering [SAICE], 2011). The N&S include maintenance guidance, encourages adoption of green technologies and specifies that sub-metering is installed in facilities to allow for utility consumption monitoring, benchmarking and maintenance. By contrast, the private sector is already investing in measuring technical and environmental performance and building maintenance (it is tax incentivised). It readily retrofits building to reduce emissions and install green technologies (in order to avoid carbon tax, to benefit from carbon credits and to reduce operational costs).

5. Discussion

SA has adopted a contextual approach to determining its new N&S. The new national guidelines, norms and standards with embedded sustainability practices identified above are published on an open, electronic repository gazetted into mandatory use in the public sector new capital work. The application notes expressly require implementation to be done with due diligence and application. Professional consultants are not absolved of their professional responsibilities of design, engineering and management, and are required to make use of the exemption processes where a conflict arises with professional judgement. Exemption processes are defined, requiring consultants to motivate deviations from the code, and this potentially provides a feedback mechanism to alert administrators of weaknesses in documentation and challenges in implementation, provided that this is actively monitored. As the N&S documentation and software is extensive, a structured capacity building and support programme is required to ensure implementation.

The current replacement rate of SA’s healthcare infrastructure is in the order of 40 years (Abbott et al, 2008, pp 146-183). In order to address building design from a life-cycle perspective a modification of the traditional roles may be indicated. For example building engineering for ventilation and climate control is sometimes limited to mechanical design solutions. Optimised passive ventilation design through building envelop design could result in a more energy- and life-cycle-efficient solutions but may require both redefining the engineer and architect’s traditional roles and methods of interaction, as well as client procurement practice. It seems likely that unless these requirements are anticipated in the pre-project stages (conception of need, briefing and contractual arrangements of consultants) that business will be conducted as usual and that conventional practice will remain pervasive.

6. Conclusion

There is a legacy sectorisation of healthcare provision split between public and private sectors with distorted investment patterns, reflected in current built form for healthcare infrastructure in SA. Emerging policy aims to improve equity and access which could result in a new generation of healthcare architecture over time but needs to be opened to innovation in infrastructure processes as well.

If it is accepted that the European approach to sustainable practice is exemplified in the single workshop, and that it is relevant to South Africa, it can be concluded that the N&S succeed partially in applying the general principles of sustainability. N&S require healthcare facilities to be designed or refurbished from a life-cycle perspective and provides some guidance on an end-of-life strategy. SMART benchmarks have been provided to minimise environmental impact over the estimated or remaining service life. A number of important healthcare-sector and contextually responsive health and comfort approaches have been incorporated. Some infrastructure is established to ensure involvement of all interested parties' and be designed or refurbished to meet the occupants' needs individually and collectively. Design, engineering and refurbishment which is user-friendly, simple and cheap to operate, with its technical and environmental performances measurable over time is discussed from a number of perspectives in the N&S.

It might be argued that the requirement that healthcare facilities be designed or refurbished to be adaptable throughout the service life, may be a "defensible exception", at least in the short to medium term given the complications described above. There are a number of sustainability criteria which may not be adequately addressed in the N&S. Whilst healthcare infrastructure undoubtedly has great social and cultural value, there is concern that sectorisation, and economic value will not be improved through the N&S, and that this is key to achieving a sustainable healthcare infrastructure platform. Finally there may not be the desired sustainable estate unless there is the introduction of a completely integrated territorial strategy in relation to both public and private sectors to attain facilities and services are accessible for all.

Developing Sustainable Energy Efficient Buildings – A Transnational Knowledge Transfer Experience between Norway and Kosovo

Abstract

As transnational institutional development programs are often advocated as a knowledge transfer opportunity between the partner universities, this case study "Sustainable Energy Efficient Buildings –Knowledge Transfer between Norway and Kosovo" investigated the knowledge transfer (KT) processes from Norwegian University of Science and Technology to College ESLG in Kosovo. An inter-organisational knowledge of transfer theoretical framework from the business sector was applied to guide the present study. The data was generated through semi-structured interviews with key university officers, professors, and students in continuous education programs from College ESLG and documentary evidence analysis from two partner universities. Based on the thematic analysis of the data, the findings demonstrated that the curriculum mapping process, joint lectures between Norwegian and Kosovar professors, joint research, and joint study visits facilitated the knowledge transfer. While the transfer of knowledge most evidently resulted in institutional capacity development for the Kosovar College unit, that managed the transnational institutional development program, the dissemination of knowledge to other units within the college was more challenging due to communication problems between the Real Estate Department and other units within the college. Hence, other universities seeking to conduct knowledge transfer through transnational institutional development programs need to understand each partner university's intention in establishing the partnerships, identify the beneficiary institutions' needs before seeking knowledge input from the partner university and improve the communication between and within the universities for sustainable benefits. The study has been part of the SEEB project supported by the HERD/Energy 2013-2015.

Keywords: transnational institutional development program, knowledge transfer, case study, Norway, Kosovo

1. Introduction

The Kosovo higher education industry includes 7 public universities: University of Prishtina, University of Prizren, University of Peja, Faculty of Islamic Studies, University of Gjilan, Kosovo Academy of Public Safety, and University of Gjakova (Kosovo Accreditation Agency, 2014). Beside this, the Kosovo Accreditation Agency (KAA, 2014) provides only a list of the evaluations of institutions (around 34) without formal decisions and there is no valuable information on the Ministry of Education, Science and Technology (MEST, 2014a). From the report published by Education, Audiovisual and Culture Executive Agency of European Union (2012) it is understood that there are 23 private higher education institutions. Most of the private and public higher education institutions in Kosovo are involved in a number of international cooperation projects supporting the establishment of new study programs or teaching improvement.

While much of literature speaks positively of the value of transnational programs in assisting institutional capacity development for universities in developing countries, there is a scarcity of empirical research that informs how these transnational programs actually facilitate actual knowledge transfer (Vincent-Lancrin, 2007; Leung and Waters, 2013). There has been limited or no research at all focusing on knowledge transfer, particularly from foreign universities to Kosovar universities through transnational institutional development programs. Therefore, it is timely to investigate the Kosovar College's perspectives about knowledge transfer from Norwegian University of Science and Technology to College ESLG through the transnational institutional development program. The uni-directional knowledge transfer from Norwegian University of Science and Technology, Norway to College ESLG took place as part of Programme in Higher Education, Research and Development (HERD) of Ministry of Foreign Affairs of Norway. Both institutions decided to cooperate in the field of energy because Norway leads in Europe in sustainable and passive buildings. In this regard, the Norwegian Parliament in January 2008, passed the law to consider imposing the passive house level for all new buildings by 2020 (Haase, 2010). In a less wealthy country such as Kosovo, households spent on average 1,210 Euros for electrical energy bills. According to the data of the Agency of Statistics of Kosovo (ASK) for 2012, around 30 percent of household expenses are spent on accommodation, a category in which electrical energy costs are included and covered. Also, Kosovo is faced with an increasing demand for electrical energy. Only during the second quarter of 2013 Kosovo used 857,7GW/h electrical energy of which households are the largest consumers of electrical energy with 56.4 percent (Efficiency for Development, 2014). The energy consumption in Kosovo homes for space heating is estimated at over 80% of total home energy consumption (Bowen et. al, 2013).

The present study focuses on the following research question:

How does knowledge transfer occur in the context of a transnational institutional development program "Sustainable Energy Efficient Buildings/HERD" from NTNU to College ESLG, Kosovo?

In attempting to answer the research question, the present study focuses at first on an inter-university knowledge transfer theoretical framework, adapted from business sector literature to guide the study, and then subsequently discusses the research methodology employed to generate the research results. After outlining the results, the discussion and implications of the study conclude the article.

2. Knowledge transfer

The theoretical framework, which is relevant to the present study, is composed of inter-organisational knowledge transfer theories developed in a business setting and complemented with the literature review on knowledge transfer in the tertiary education (Courtney and Anderson, 2009). Although the term knowledge transfer is used extensively in the modern literature, it is very important to explain what is meant by knowledge transfer as used in the present study. The knowledge transfer is defined as ‘‘the process through which one unit is affected by the experience of another’’ (Argote and Ingram, 2000, pp151).

According to Bauman (2005), the transfer of knowledge means the modification of existing knowledge from a sender organisation (for instance Norwegian University for Science and Technology) for the purpose of addressing issues that a receiving organization (in the context of this research College ESLG) faces. Inter-organisational theories of knowledge transfer argue that knowledge transfer takes place in four stages such as: 1) intention to engage in knowledge transfer through expressing of intention either from the sender organisation or receiving organisation to engage in transnational institutional development program; 2) the structured process of knowledge transfer; 3) the unstructured process of knowledge transfer and 4) the institutional capacity development (Chen and Mc Queen, 2010).

The inter-organisational theories of knowledge transfer argue that at the inter-university level, knowledge transfer begins with the intention of either party to engage in a transnational institutional development program, which explicitly results in a formal agreement or application for a donor-funded program. Robertson and Jacobson (2011) argue that research in the business sector shows that the expression of the intention to either acquire (receiving organisation) or share knowledge (the sender organisation) is critical to knowledge transfer. Both authors argue that the intention to engage in knowledge transfer must be mutual. The receiver organisation must explicitly exhibit the intention to acquire knowledge, whereas the sender organisation also must have the intention to share knowledge (Easterby-Smith et al. 2008). Eldridge and Wilson (2003) further argue that both institutions of higher education must show a genuine interest to engage in knowledge transfer. Huang (2007) argues that for any knowledge transfer to be successful in any transnational institutional development program, both partners must clearly specify the types and scope of knowledge transfer.

A structured process of knowledge transfer includes four phases (Szulanski, 1996). There are: initiation, implementation, ramp-up, and integration. The initiation phase usually takes place by identifying the knowledge gaps in the beneficiary institution. The knowledge gaps must be identified clearly in the partnership agreement. If the knowledge gaps are clearly identified at the initiation stage, then the implementation takes place much more smoothly. During the implementation phase, both institutions work together to ensure that the knowledge shared is what was shared between two universities and that it is also appreciated and valued by the receiving institution. The ramp-up phase follows with the staff members of the receiving university applying the acquired knowledge and resolving the knowledge gaps. Finally, at the integration phase, the acquired knowledge is institutionalized through the production of documents such as course syllabi, teaching methodology manuals and dissemination of the produced documents to other units of the university (Flores et al. 2012).

The knowledge transfer process may also be unstructured, which takes place in a spontaneous, informal, and unplanned manner (Chen and McQueen, 2010). The unstructured process of knowledge transfer depends on arising situational demands and individual dispositions. The unstructured process of knowledge transfer includes copying pre-existing knowledge products from the partner university and adapting that knowledge to the new context of the receiving university, independent of the sender university. In the unstructured knowledge transfer process, lecturers exchange knowledge without formal agreements, and the knowledge acquired can be applied individually or collectively by the lecturers (Chen and McQueen, 2010). In order for the knowledge which was acquired through the unstructured process to be retained and further shared within the institution, the recipient university must institutionalise the knowledge gained through production of documents at the institutional level. Then the knowledge gained through unstructured process has to be merged with the knowledge transfer that takes place through a structured process. This takes place during the integration stage (Argote et al. 2003). Whereas the theoretical framework proposes the unidirectional flow of knowledge usually from the sender to recipient university, authors such as Courtney and Anderson (2009) argue that the knowledge transfer takes place in a bidirectional way and requires interaction between the partner universities to fully appreciate the knowledge being transferred.

3. Methodology

A qualitative research method is used to explore the real interest of complex situations in the planning, which cannot be easily quantified. The qualitative research approach enables us to find reliable answers for research question posed. The qualitative method can provide the intricate details of phenomena, which can´t be derived through quantitative methods (Strauss and Corbin, 1990). The qualitative research technique is a more intrusive technique and less structured as the quantitative method, which enables the interviewer to gain in depth insight regarding the research topic (Jarrratt, 1996).

The present study uses qualitative research method, which includes semi-structured interviews and consultation of documents as two data sources. In total, 120 participants were invited to respond to semi-structured interviews. Out of 120 participants, 108 responded successfully. The successful respondents were: T3 professors from Kosovo participating in the Sustainable Energy Efficient Project, the chancellor of the College, 3 master students who spent one semester at NTNU as students and later, upon graduation, became teaching assistants at ESLG, 10 students who participated in the study visit in Norway, 60 master students who attended lectures that were jointly held by NTNU and College ESLG professors, and 31 participants from the ranks of other stakeholders that participated in conferences and symposia organised by both institutions. The respondents were selected from the ranks of those that were directly involved in the project and knowledge transfer. Although four professors from ESLG were foreseen to participate in the SEEB project according to initial application, only three were involved in all phases of knowledge transfer and throughout the duration of the project. Ultimately, ten students participated in the study visit in Norway and all of them were selected as respondents. These ten students include also three students that took place in a semester exchange, however, the three students participating in two different categories were asked two sets of questions (one regarding knowledge transfer achieved through study visit and the other one regarding knowledge transfer achieved through spending one semester). Also, sixty students were selected from two generations of students that attended lectures and courses with NTNU professors. Forty students were selected from the group of forty students enrolled in the master program of Real Estate Management in academic year of 2013/2014 and twenty students were selected from the class of twenty students enrolled in the master program of Real Estate Management in academic year 2014/2015.

Finally, thirty one respondents that were selected from the stakeholders group were selected from the group of two hundred people who took place in conferences and symposia organized jointly by NTNU and ESLG. Thirty one respondents were selected in the way that they represent main stakeholders such as Kosovo institutions (Ministry of Energy and Ministry of Environment and Spatial Planning), local government (directorates of urbanism of Kosovo municipalities), private sector (construction companies), professional associations in the field of energy efficiency, and various international donor agencies. The names of the participants were coded. The students were grouped into three categories: 1) students that completed one semester at NTNU and upon graduation were promoted to teaching assistants at the recipient university and who also did the master theses with Norwegian professors; 2) students that participated in a study visit in Norway and 3) students who attended lectures with NTNU professors in Kosovo. Table 1 describes the types of respondents, code numbers and their characteristics.

Table 1: Types of respondents, their code number and characteristics

Respondents type/category	***Code number***	***Characteristics***
Professors	*PROF*	*Only planners with ten years of experience that worked in municipality of Prishtina immediately in the period after the war*
Chancellor	*CHAN*	*Chancellor of the College as part of executive of College*
Students that completed one semester at NTNU	*$STUD_1$*	*Only students that completed one full semester at NTNU and completed their theses with Norwegian professors.*
Students that participated in study visit	*$STUD_2$*	*Only students that participated in a study visit at NTNU*
Students that attended lectures with NTNU professors in Kosovo	*$STUD_3$*	*Only students that attended direct lectures by Norwegian and Kosovar professors jointly in Kosovo for a full course*

Other stakeholders involved in the project	*STAK*	*Other stakeholders that attended the transfer of knowledge through organisation of conferences and symposia*

The categorisation of cases is presented in Table 2.

Table 2: Categorisation of cases

Category code	***Category description***	***Case identification code***
PROF	*Professors of ESLG*	*C1, C2, and C3*
CHAN	*Chancellor*	*C4*
STUD1	*Students that completed their semester at NTNU*	*C5, C6, and C7*
STUD2	*Students that completed their study visit in Norway*	*C8 to C 17*
STUD3	*Students that attended lectures with NTNU professors in Kosovo*	*C18-C77*
STAK	*Other stakeholders that attended conferences and symposia*	*C78-C108*

The interviews were conducted in Albanian and translation by a certified translator from Albanian into English was provided. The second source of data was the selected recipient college documents pertinent to the transnational institutional development program “SEEB”. These documents consisted of an application for the SEEB project funded by the HERD program of Ministry of Foreign Affairs of the Kingdom of Norway, annual reports from the SEEB project, curriculum documents such as course syllabi, conference agenda, filled student survey forms, conference participant’s feedback, and transcripts of meetings of the Steering Committee of the SEEB project. In the present study, the documents were categorised as secondary data used to corroborate the primary findings from the interview data.

The key constructs of intention to engage in knowledge transfer were; 2) the structured process of knowledge transfer; 3) the unstructured process of knowledge transfer and 4) the institutional capacity development were examined as specific themes used to investigate the date. Excerpts from the interviews discussing those thematic areas were compared and carefully examined. While there are excerpts relevant to these predetermined thematic areas, there are also excerpts from interviews that do not support the predetermined themes. In the end of analysis of interviews, the themes are determined as dominant if they show up in more than 50 % of the responses of semi-structured interviews. Furthermore, the dominant themes were used to analyse the secondary source of data such as documentary evidence. In order to enhance the credibility of qualitative studies, the triangulation technique was used (Guba, 1981). In order to ensure the triangulation, parts from the documents in line with the dominant themes were grouped together in order to support the dominant themes, which enabled triangulation of the findings from the semi-structured interviews and the findings from the documents.

4. Research results

The present study shows how College ESLG responded to the knowledge transfer processes generated by the Sustainable Energy Efficient Buildings Project (SEEB)/HERD program. College ESLG was a good partner for this project, as the first faculty in Kosovo teaching and researching in the field of Real Estate Management, and with tradition of cooperating with international institutions from Slovenia and USA. Both institutions were interested to develop creative cooperation in the field from research and teaching perspective.

The study found that the Norwegian University for Science and Technology and College ESLG were involved in a structured knowledge transfer process, which means that both parties began negotiations at the initiation stage to apply for a joint project of institutional development of the college in the Western Balkans. Within College ESLG, the project coordinator C3, who is responsible for initiation of international projects within ESLG expressed the following:

> "Yes we engage in a structured process of initiation of collaboration projects with foreign universities. It all begins with the letter of intent and then a memorandum of understanding is signed. Before signing any agreement, we at ESLG identify the areas in which we need support from the foreign universities. It is in our vision to engage in collaborative projects with strong universities that come from the developed countries, from which we can benefit in terms of gaining the necessary knowledge".

Also upon negotiations between College ESLG, NTNU and Multiconsult, the parties signed the memorandum of understanding and also the application for an institutional development project entitled "Sustainable Energy Efficient Buildings" funded by the HERD program of the Ministry of Foreign Affairs of the Kingdom of Norway. As can be seen from the extract below, institutional development, curriculum development, and research capacity development were identified as key areas for knowledge transfer. A two-way interaction was needed to prepare the application for the SEEB project.

Main objectives of the project Sustainable Energy Efficient Buildings are to develop the institutional capacity of ESLG on energy efficient buildings and sustainable refurbishment. This include development of a master study program energy management in Buildings, develop research capacity at ESLG on energy efficient buildings and sustainable refurbishment, and building a network among academia, the construction industry, and authorities in Kosovo (Application for SEEB project, pp4). While the written application for project SEEB documented the jointly agreed intentions to engage in knowledge transfer on both sides, the views expressed by participants (case 1 to case 3) through interviews were not consistent with the written documents. For case 1 to case 3, establishing transnational institutional development program was unidirectional and seen as a way to seek and develop the institutional capacity of ESLG in the area of energy efficient buildings and sustainable refurbishment, as exemplified by the following excerpt.

C1 notes the following: "From the very beginning although the application for SEEB project provided for bi-directional knowledge transfer, we as ESLG were hoping to have more uni-directional knowledge transfer in the field of curriculum development, teaching methodology, research capacity development, and grading standards in the area of energy efficient buildings and sustainable refurbishment, where Norwegians lead in the world. It was our intention to acquire as much knowledge as possible from Norway in order to transfer it further to other stakeholders such as students, authorities, and construction industry". In the above excerpt, we can see the expectation of College ESLG to engage in knowledge transfer that was clearly seen from expressions like ''unidirectional transfer of knowledge'' and ''transfer it further to other stakeholders''. For participants at the school level, as represented by College ESLG Lecturer 1 above, the way to engage in knowledge transfer and development of institutional capacity was through curriculum collaboration with Norwegian University of Science and Technology. From the above excerpt we can see the expectation of College ESLG to have the knowledge transfer through curriculum development collaboration, development of teaching methodology through joint teaching and development of research capacity.

Nevertheless, in the application for the SEEB project we see that the knowledge transfer was planned to take place bi-directionally because also three Kosovar professors were planned to teach at NTNU so students and professors of NTNU also gain some insight about the teaching methodologies that are practised in Kosovo.

Following the initiation stage, the universities moved to the implementation stage. Regarding the teaching methodology collaboration, professors of ESLG that were involved in the project reported positively that they learnt a lot with regards to transfer of knowledge in teaching methodology development.

> "The focus of Norwegian professors on practical methods "learning by doing" has facilitated my teaching process with students of ESLG later. I introduced the same teaching process that Norwegian professors used in the courses I teach" (Case 2).

In the development of teaching methodology through co-teaching and teaching collabolation, all respondents both professors and students think that the same effect would have not been achieved had the professors from Norway stayed only as quality assurers and not as co-teachers too.

C2 noted the diversity of teaching methodologies enriches the experience in the classroom, whereas C3 stated the following: "The methods of co-teaching are not a method of teaching in our country, and I think that this method should become a practice in all our higher education institutions in order to improve the quality of studies. The co-teaching brings more transferable knowledge".

From the category of cases $STUD_1$, C5 notes the following:

> "Through co-teaching a comparative analysis between the situation in Norway and Kosovo was drawn. In this way we were able to acquire more knowledge that now we will be able to transfer it further to other students in our capacity as teaching assistants"

Regarding transfer of knowledge through curriculum development, the answers can be exemplified by the following excerpt:

> "The curriculum development collaboration took place in a structured and unstructured way. The structured way was also foreseen by the application for SEEB project to develop together a master program in Energy Management. Due to requirements of Kosovo Accreditation Agency, the collaboration was focused on development of curriculum for the study program of Energy Management. Norwegian professors submitted us the course outlines and then we developed further the learning outcomes based on the needs of construction industry of Kosovo" (Case 1).

The knowledge transfer through curriculum development capacity is also foreseen in the original application for SEEB project, which states that one of main objectives is to develop the curriculum for the study program of Energy Management at master level (Application for SEEB project, pp5). Nevertheless, the transfer of knowledge in the curriculum development was not an import of everything from Norway. As C1 notes: "Not everything was copy pasted. We customised many of the course syllabi of the Energy Management program to the needs of Kosovo. In other courses of the Real Estate program we tried together to make comparative analysis between situation in Norway and Kosovo with regards to energy efficient buildings".

In this regard nearly all respondents, both professors and students agree that they benefited a lot from the collaboration between Norwegian and Kosovo professors in curriculum development and they appreciate the comparative analysis between Norway and Kosovo. Students responded that they benefited from teaching techniques of Norwegian professors, course syllabi, updated suggested literature, and exercises with different software. In this regard, professors noted that they benefited from joint curriculum development, definition of course objectives and learning outcomes, discussion on literature list for courses, organisation of joint conferences, production of case studies for the courses, and joint assessment of students' research papers and final examinations according to NTNU assessment methods and guidelines. The curriculum mapping process took place through exchange of documents and discussions between Norwegian and Kosovo professors. C2 notes: "We participated fruitfully in an exchange of emails and documents regarding curriculum of Energy Management study program". This is corroborated also by a documentary evidence of transcripts of minutes of the Steering Board of Project SEEB (Minutes of Steering Board of SEEB project, June 2014 – October 2014).

With regards to transfer of knowledge through exchange of students for one semester at NTNU, C5 to C7 all agreed that they benefited a lot in transfer of knowledge especially through practical work in the laboratories of NTNU through involvement of people from the practice in the lectures of NTNU and lectures from practice work at Multiconsult in Oslo. The transfer of knowledge through study visits can be exemplified with the following interview excerpt from case 5:

> "The study visits were a direct benefit for both students of ESLG and professors. The most important thing was to attend lectures in the company Multiconsult and hear people who are involved in direct practical projects. Also visiting the Zero Emission Building Power House in Oslo was a direct knowledge transfer. All the things we have learnt for one semester in

theory in sustainable architecture we learnt through a two hour study visit in that facility" (Case 5).

In terms of knowledge of transfer in research capacity development, the respondents do not think that the transfer happened successfully although it was one of main objectives of application for SEEB project (Application for SEEB project, pp4). All the cases from C1 to C3 stated that they did not have any opportunity to work together in research publications with Norwegian professors. C1 to C3 argue that the research capacity collaboration took place more in an ad-hoc way rather than in a structured manner.

With regard to knowledge transfer through joint conferences and symposia, respondents from the construction sector categorised with the code STAK agree that they learnt a lot from presentations of Norwegian professors. C88 noted the following: "I learnt a lot from the presentation regarding design of zero emission buildings and design of climate adapted buildings". Nevertheless, few of the cases were critical of the content of conferences because as they say they wanted to hear more about sustainable building materials and technologies rather than general concepts of refurbishment.

In the integration stage, the extent of knowledge was rather limited to the level of program of real estate. Regarding integration stage C1 noted the following: "We worked very well in other stages but we did not work together to produce documents that would serve as manuals or documents that we could use college wise. We were supposed to establish a Center of Energy Efficient Buildings, where all the acquired knowledge during the SEEB project would have been transferred to, but we failed to established the center properly due to lack of funding, although the application for SEEB project provided for the establishment of such a center within ESLG. We were able to develop and accredit a study program in Energy together but failed in the establishment of the center".

5. Discussions

The discussion of the present study centres on main findings. Firstly, the present study found the partners' main intentions in establishing the transnational institutional development program were clearly understood by each other. On the other hand, the study found that knowledge transfer occurred through curriculum development collaboration —a structured knowledge of transfer process which was mandated by the application for SEEB project. The study found that also the knowledge transfer occurred through joint teaching of Norwegian and Kosovo professors and although the original role of Norwegian professors as foreseen by the application for SEEB project was to serve as quality assurers, the deviation from the application in ensuring higher teaching collaboration between Norwegian and Kosovo professors turned out to be positive.

ESLG and NTNU had similar aspirations, as presented in the project application for SEEB, which upon project implementation resulted in solid knowledge transfer to Kosovo professors and students. In this regard Leing and Waters (2013) argue that contrasting aspirations between partnering universities in a joint project are the main cause for termination of the partnership and elimination of further knowledge transfer opportunities within the partnership. Mercer and Zhegin (2011) argue that universities must comprehend what each partner university seeks in the joint project or program in order for mutually beneficial activities to be developed and sustained. It is noted that this mutual comprehension took place between ESLG and NTNU and third partner Multiconsult.

On the other hand, although the research capacity development was foreseen to take place according to the application for the SEEB project and annual reports from the SEEB project, the study found that the research capacity development was not properly achieved. Contrary to this, the transnational programs can be seen as one of the main means for knowledge transfer from the foreign university but not the only means available (Gilbert and Gorlenko 1999). In the integration stage, the study found that there was no dissemination of knowledge transfer beyond the level of real estate program to the other units. Omerzel et al. (2011) argues that one way to ensure the retention, documentation, and accessibility of knowledge beyond individual lecturers' knowledge base, is the development of a knowledge management system. The study found that this did not happen as part of the project where all knowledge transfer would be documented.

6. Conclusions

The present research, with the focus on the knowledge transfer in the context of a transnational institutional development program SEEB from NTNU to College ESLG, shows a positive correlation between two institutions. From the findings, all four stages of knowledge transfer were covered: intention to engage in knowledge transfer, the structured process of knowledge transfer; the unstructured process of knowledge transfer and the institutional capacity development. The cooperation was as bi-directional knowledge transfer; however the present research focuses only on the uni-directional knowledge transfer from Norwegian University of Science and Technology to College ESLG. With the help from NTNU a new study program was developed, customised to the needs of Kosovo. Joint teaching of Norwegian and Kosovo professors in Kosovo and students study experiences in Norway was evaluated as a very positive case of knowledge transfer. Both professors and students enriched the College ESLG with their academic and research experiences.

To conclude, knowledge transfer occurred mainly through a structured process which was arranged in the application for project SEEB. Although one of the tasks to establish a Centre for Energy Buildings did not materialise due to the lack of funding, research activities were provided through different ways. The SEEB project has contributed to an institutional development and knowledge transfer for education and research in the field sustainable energy efficient buildings in Kosovo.

Impact of Prior Distributions of Energy Model Inputs on Prediction of Building Energy Retrofits

Seong-Hwan Yoon and Cheol-Soo Park

School of Civil and Architectural Engineering, SungKyunKwan University, Korea
Email: ecoshyoon@gmail.com

Abstract

In order to reduce the performance gap between the reality and energy prediction, Bayesian calibration of building simulation models have been highlighted since it can take into account the stochastic nature of building systems. However, for the use of Bayesian calibration, quantification of prior information on uncertain inputs is a prerequisite. In general, the prior information on the uncertain inputs are not well established in the literature. Therefore, uncertain inputs are usually determined by subjective judgment of simulation users.

However, the results of Bayesian calibration can be significantly influenced by the prior distributions of simulation inputs. In this paper, the authors aim to assess the impact of the prior distributions of simulation inputs on Bayesian calibration of a given energy model and decision making of building energy retrofits. The author performed Bayesian calibration using two different prior distributions (uniform and normal). Then, two different prior distributions were propagated. Based on the propagated simulation outputs, decision making of building energy retrofit scenarios was studied. It is concluded that the decision making of energy retrofits is significantly influenced by the prior distributions of inputs.

Keywords: Building Energy Simulation, Energy Retrofit, Calibration, Bayesian, Prior Distribution

1. Introduction

It is important to have an accurate energy simulation model since it predicts the effect of Energy Conservation Measures (ECMs) for existing buildings. In developing an energy simulation model for existing buildings, a calibration technique must be introduced because in existing buildings, many unknown inputs usually exist such as infiltration, internal heat generation from people, lights and equipment, indoor room air temperature, etc. Such inputs are usually not deterministic but stochastic.

The model calibration is a process of estimating uncertain inputs to reduce the gap between the actual building energy consumption (observed data) and the predicted value of the simulation model (model output) (Hensen et al, 2012). A number of studies have been conducted on the model calibration and parameter estimation. Recently, a Bayesian inference method has been highlighted since it can take into account the uncertainty of the building' thermal behavior. Tarlow et al (2009) introduced a Bayesian network to construct a simulation model and estimate a building energy consumption. Hawarah et al (2010) proposed a method to predict occupant behavior and energy consumption in residential dwellings based on Bayesian network. Carbonari et al (2014) used a Bayesian network to construct a system model and predict the future state of the system for supporting the model-based optimal control. Booth et al (2012) used a Bayesian calibration method for quantifying the uncertainty in housing stock models. Yan (2013) used Bayesian statistics to predict the energy consumption of a building and performed a diagnosis of the building control systems. However, Bayesian inference results are dependent on prior probability distributions of inputs. Heo et al (2015) found that a Bayesian calibration is influenced by a different information (data) level. Riddle et al (2014) discussed the limitations caused by the size (number) of observed data.

This study aims to investigate the impact of 'prior probability distributions of inputs' on the building energy model. In this study, the authors applied two different assumptions (uniform and normal) with regard to prior probability distributions of inputs. Then, the impact of such assumptions was analysed. Please note that the aim of this study is not to find accurate prior probability distributions of each input, but to identify the influence of such assumption on decision making of energy retrofits.

2. Bayesian Calibration

The calibration methods are divided into a deterministic and a stochastic method. The deterministic method uses an optimization algorithm to search for a set of unknown inputs which minimizes the difference between observed data and simulation prediction (Carroll et al, 1993; Park et al, 2004; Ascione et al, 2011; O'Neil et al, 2012; Dong et al, 2014). However, the deterministic approach tries to find a set of inputs that minimizes an objective function in the optimization process. Therefore, it cannot take into account the stochastic nature of inputs.

For the stochastic calibration, Bayesian inference has been widely used due to the recent improvement of computational speed and development of Bayesian inference techniques (Bishop, 2006). The Bayesian calibration quantifies uncertain inputs in the energy model as probability distribution as well as to propagate the effect (uncertainty) to the output of the simulation model. The Bayesian method requires information on prior probability distributions of uncertain inputs. However, since such information is not well established in the literature, prior probability distributions of uncertain inputs are assumed to be a normal distribution in most studies.

Bayes' theorem is as shown in Equation (1). The posterior distribution can be estimated as a product of the likelihood function and the prior probability distribution.

$$p(\theta|y) \propto p(\theta)p(y|\theta) \qquad (1)$$

where
θ : calibration inputs
y : observed data
$p(\theta)$: prior distribution of inputs
$p(\theta|y)$: posterior distribution of inputs
$p(y|\theta)$: likelihood function

Kennedy and O′Hagan (2001) reported a Bayesian calibration method (hereafter referred to as KOH method) as shown in Figure 1. The relationship between the observed data ($y(x)$), a true system response ($\zeta(x)$) and the simulation model prediction ($\eta(x,\theta)$) is expressed as shown in Equation (2).

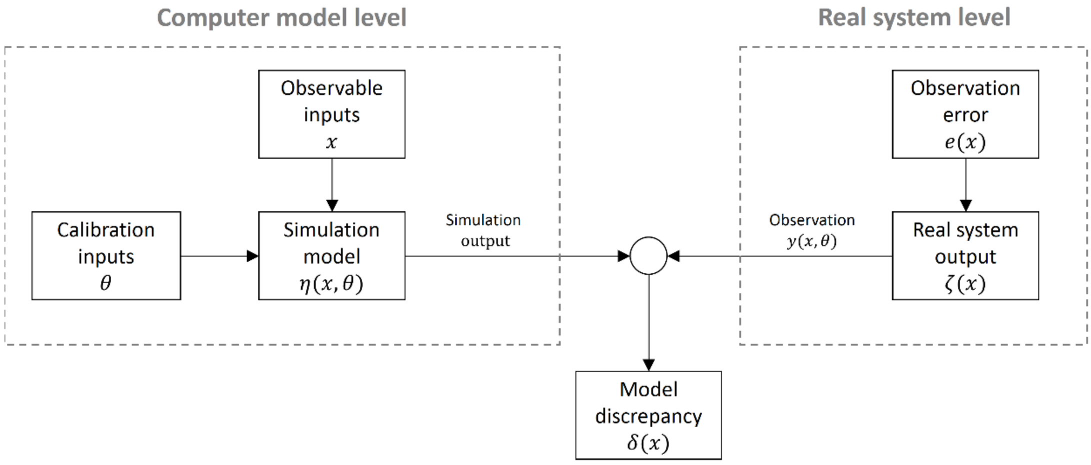

Figure 1. Bayesian Calibration Framework developed by Kennedy and O'Hagan (2001)

$$\begin{aligned} y(x) &= \zeta(x) + e(x) \\ &= \eta(x,\theta) + \delta(x) + e(x) \end{aligned} \quad (2)$$

where
x : observable or controllable inputs
$\zeta(x)$: true system response
$\eta(x,\theta)$: simulation model prediction
$y(x)$: observed data
$\delta(x)$: model discrepancy between $\zeta(x)$ and $\eta(x,\theta)$
$e(x)$: observation error

3. Target building

The target building (Figure 2) is an office building located in South Korea. The building's gross floor area is approximately 8,415m^2. The simulation model was generated using DesignBuilder.

Then, uncertainty analysis, sensitivity analysis and Bayesian calibration were performed using MATLAB script files, executing a batch run of EnergyPlus simulation.

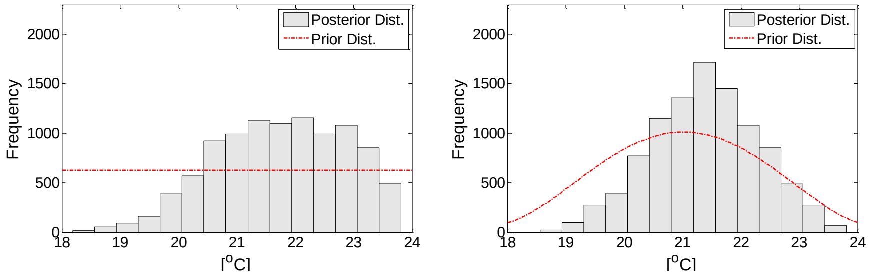
Figure 2: Target Building (left) and simulation model (right)

The values of inputs and their ranges (minimum value, maximum value) were first sought based on the literature (Macdonald, 2002; ASHRAE, 2013a; ASHRAE, 2013b; Hosni et al, 1999; Persily, 1998; CIBSE, 2006; ASHRAE, 2007; Guadalfajara et al, 2012; Garmsiri et al, 2014). In this study, the following inputs were treated as uncertain: thermal properties of the building's envelope (conductivity [W/mK], density [kg/m^3], specific heat [J/kgK] of opaque parts, U-value[W/m^{2}K], SHGC[-] of transparent glazing), occupant density [person/m^2], sensible and latent heat from people [W/person], lighting density [W/m^2], equipment density [W/m^2], operation hours [h], heating and cooling set point temperatures[°C], infiltration rate [m^3/s.m^2], ventilation rate [m^3/s person], fan efficiency[-], pump efficiency[-], heating and cooling system's efficiency[-], elevator electricity use [W].

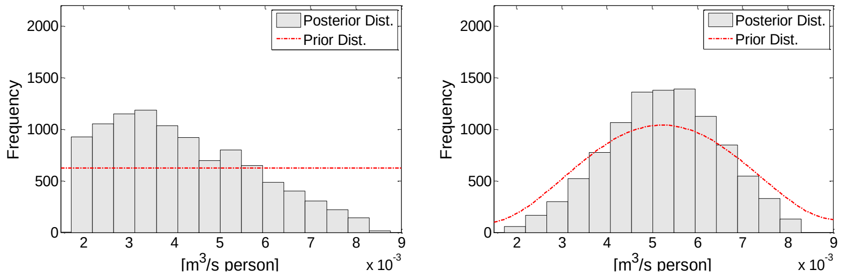
Morris method (Morris, 1991) were used to find dominant inputs. In Morris method, the influence of inputs on the output is determined using Elementary Effect (EE). The mean of EE for each parameter represents the influence on the simulation output. As the result of Morris method, top eight dominant inputs were selected as follows: heating set point temperature, infiltration rate, cooling set point temperature, occupant density, ventilation rate, equipment density, lighting density, absorption chiller's efficiency.

4. Comparison of posterior probability distribution

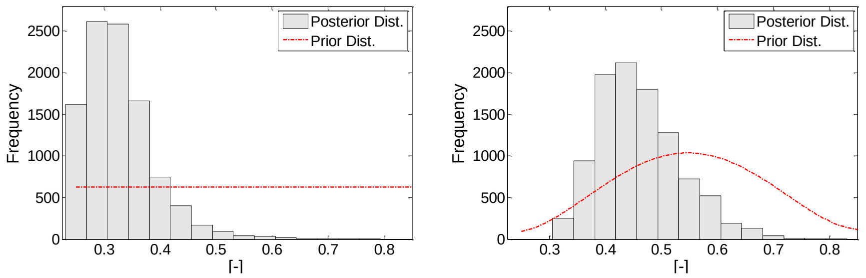
Bayesian calibration was carried out based on two different prior probability distributions of inputs (uniform, normal). The results of calibration (the posterior distributions of inputs) are shown in Figure 3.



(a) Probability distribution of heating set point temperature (left: uniform, right: normal)



(b) Probability distribution of ventilation rate (left: uniform, right: normal)



(c) Probability distribution of absorption chiller efficiency (left: uniform, right: normal)

Figure 3: Comparison of posterior distributions

As shown in Figure 3, the posterior distributions of inputs differ from each other. When the prior distributions of inputs were expressed as a uniform distribution, the estimated posterior distributions are not similar to uniform distribution but are inclined towards either the minimum or the maximum. On the other hand, when the prior distributions of inputs is assumed to be in a normal distribution, the posterior distributions are similar to a normal distribution.

5. Comparison of energy retrofits

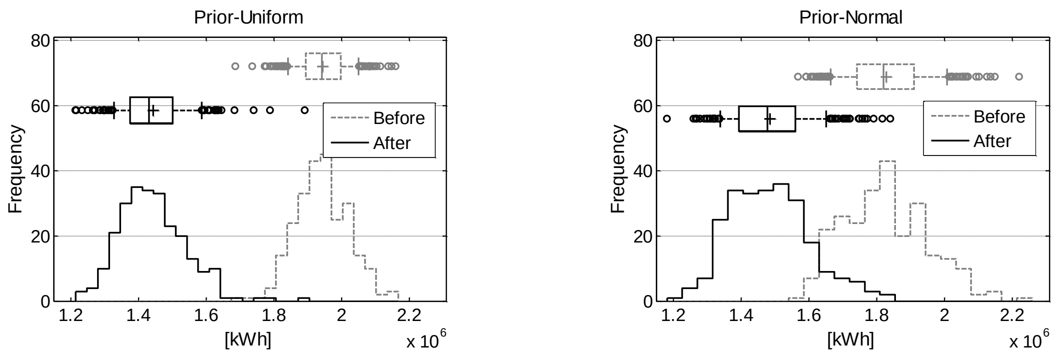
The ECMs of the target building are summarized in Table 1. The old windows are to be replaced with new windows. New windows were selected based on ASHRAE (2013b). The old absorption chillers are also to be replaced with new efficient ones.

Table 1: Energy retrofits

ECMs		before	After
replacement of windows	U-value	4.0 W/m^2K	1.12 W/m^2K
	SHGC	0.65	0.23
Replacement of Chillers	COP	Figure 3(c)	0.75

Figure 4 shows energy consumption distributions of design alternatives before and after retrofit. The expected energy consumption distributions are different from each other according to the prior distributions. When the prior distributions of simulation inputs are set to a normal distribution, the range of the uncertainty becomes greater (Figure 4(b)). It is noteworthy that there is an overlapped area between before and after the retrofits.

The determination of the range and distribution form is an unresolved issue in building energy simulation (Tian, 2013). The probability distribution of uncertain inputs need to be defined before performing stochastic analysis (e.g. uncertainty analysis, sensitivity analysis, stochastic calibration). However, prior information or knowledge with regard to uncertain inputs are not well established (de Finetti, 1974; Gao and Chen, 2005; Qiu et al, 2014). In previous studies (Booth 2012; Heo 212; Tian, 2013), the ranges or distributions of inputs were mainly dependent on the level of information and subjective judgment by experts. It can lead to inaccurate prediction of retrofit alternatives. The retrofit decision must be based on the objective and validated prior distribution. The prior distributions of uncertain inputs are usually determined by simulation users' subjective judgment and therefore, decision making of energy retrofits based on such outcome can be biased.



(a) Prior distribution – Uniform *(b) Prior distribution – Normal*

Figure 4: Energy consumption distributions before and after retrofit

6. Conclusion

The paper reports a Bayesian calibration study investigating the impact of assumptions on the prior distributions of uncertain inputs. It is concluded that if there is no enough information on uncertain inputs, the energy model prediction can be biased depending on the assumption of prior distributions of inputs. At present, if Bayesian calibration is to be applied to the simulation model of existing buildings, careful attention should be paid to the assumption of the prior distributions of inputs. As a future study, the data collected through the Building Energy Management System (BEMS) can be utilized in order to overcome the aforementioned disadvantage (lack of knowledge about uncertain inputs).

Abstract

There is a diversity of factors responsible for inspiring green infrastructure action which can work either independently or in combination with one another; however, the South African built environment has been slow in adopting and implementing green principles in building construction projects. The lack of evidence with respect to green progress may suggest that indicators for assessing the performance of green buildings are not yet at the forefront of the construction industry agenda. This paper emphasises that green building benefits are real, and also shows the decision maker that even though there are risks factors involved when going green, there are critical factors and indicators as well, to ensure the successful implementation of green building. The purpose of this paper is to develop a framework aimed at promoting the growth of green building. The proposed framework is synthesised from a review of literature and current best practice. The framework suggests 31 performance indicators, the presence of which may assist construction industry stakeholders in pursuing the green agenda. The indicators can also be useful to monitor progress towards the economic, social and environmental goals of going green. This paper is part of on-going research, which aims to investigate the critical factors that inhibit the growth of green building in the South African built environment in order to accelerate the understanding and implementation of green infrastructure in the country.

Keywords: Criteria, green building, evaluation, performance indicators, sustainability

1. Introduction

As the field of green design evolves, various research studies (see Srinivas, 2009; Furr 2009; Naumann *et al.*, 2011) are focusing on measuring the actual benefits of these designs, thus the performance of buildings that are considered ‘green’. Numerous projects in the United States of America (USA), and other countries are attempting to define the qualitative and / or quantitative measures of green buildings, and the data needed to implement and assess these measures. These relentless efforts are important to determine whether the expected impact on human health and the environment has been achieved, and the related additional cost or saving (Todd & Fowler, 2010). Many types of tools are available to the construction industry, including sustainability assessment indicators, used for providing summaries and to focus and condense the complex surroundings into a form of manageable indicators (Suopajarvi, 2011). Building rating systems, also known as ‘building rating tools’ are one such type of sustainability assessment indicator. Green building cost and performance metrics (Todd & Fowler, 2010), the metrics include measurements for the cost and performance impact of water, energy, maintenance and operations, waste generation, purchasing, occupant health and productivity, and transportation. The metrics and protocol are being applied in the USA where green building designs are compared to similar buildings with more historically typical designs (Todd & Fowler, 2010). According to Gibberd (2011), the objectives of and criteria for green building designs should integrate environmental, social and economic performance requirements. In addition, the objectives and criteria should be aligned with good practice and government policy. However, studies demonstrates that historically green building performance indicators have been predominantly developed to assess some environmental issues and that, few of them could currently be considered to adequately assess the full range of sustainability issues (Lowe & Ponce, 2009; GBCSA-WGBC, 2013). On the socio-economic front, very little research has been undertaken to ascertain the linkages between green building practices and the socio-economic performance of green buildings, especially in the long term for purposes of sustainability evaluation (Kalua, 2015; Kamali & Hewage, 2015), and particularly in the context of developing countries. The reasons for this are in themselves, a potential area of further research but are likely to be, at least partially, due to the fact that environmental issues are typically easier to quantify and can therefore be assessed objectively. However, social-economic sub-issues are often difficult to assess either relying on subjective judgment, or complex calculations which do not sit well in assessment systems that aim to be objective and time / cost effective to use (Lowe & Ponce, 2009).

In the context of South Africa, the Green Building Council of South Africa (GBCSA) released its first assessment tool that improves or has the potential to improve environmental performance during the design and construction phase (GBCSA, 2014a). Furthermore, it should be noted that the GBCSA has also released its existing building performance tool for pilot application. The credits of the rating tool fall within three broad categories, and will consider measurable performance indicators such as water, energy and waste management, lease agreements, management contracts or procurement policies that define performance requirements, and building attributes that inform performance (DPW, 2013; Business Report, 2013). The rating tool will address demand from an entirely new segment of the property market in South Africa and allow effective and objective measurement of an existing building’s environmental performance in operation. However, specific design solutions with respect to how to achieve key performance indicators have not been prescribed (Business Report, 2013). Most recently, the GBCSA has also released Green Star SA Socio-Economic category indicators for piloting (GBCSA, 2014b). The Socio-Economic Category Framework has been established with key considerations and boundaries, such as building scale, stage of life, prioritisation, and objective assessment measures. The framework in terms of building scale addresses individual buildings only, excluding community, precinct or neighbourhood projects (GBCSA-WGBC, 2013). In terms of stage of life, the framework focuses on what can be

achieved mainly through the design and construction phases. However, the framework does not address the long-term operational phase of the building (GBCSA-WGBC, 2013).
These challenges reflect the need to develop an all-inclusive indicators that are based on accurate scientific data as well as indicators that are easy to understand for the public and decision-makers (Sustainable Cities International, 2012).

Against this backdrop, the aim of this paper is to develop a framework aimed at promoting the growth of green building by establishing the need to engage with the balance of environmental issues as well as economic and social imperatives. This is a review paper and it significantly draws from reviews of literature deemed to be relevant to the aforementioned aim. The study is grounded in the context of developing countries such as South Africa. In order to enhance the growth of green building, monitoring and evaluation of green building performance should be carried out. It will also be necessary to establish a baseline of building typology performance, formulate an appropriate set of national indicators, measure progress in building performance, measure compliance to annual targets, and to project a trajectory toward meeting national goals (DPW, 2011). Gibberd (2002) affirms that to facilitate the application of knowledge developed, as well as the monitoring and evaluation of green building assessment, indicators, rating and labelling systems specific to Africa is required. Although the CSIR has developed an assessment system (see Gibberd, 2002) suitable for use in Africa, it relies on the further development of indicators specific to the challenges experienced on the continent (Du Plessis, 2005).

2. Research methodology

The research methodology adopted for this paper was to conduct a critical review of the literature, which explored key performance indicators for green building mainly on the basis of academic literature. According to Fink (1998), "A literature review is a systematic, explicit, and reproducible design for identifying, evaluating, and interpreting the existing body of recorded documents." The analysis of documents pursues the aim of uncovering material that does not have to be created on the basis of data collection by the researcher. The objective for surveys of the literature are two fold; firstly, to summarise existing research by identifying patterns, themes, and issues. Secondly, this helps to identify the conceptual content of the field (Meredith, 1993) and can contribute to theory development. This study also follows a deductive approach. According to Goodwin (2002), a deductive approach takes the form of top-down reasoning from more general (by developing theory) to the more specific, whereas the inductive is the bottom-up logical process of reasoning from the specific to the general (theory). Mouton (2001) contends that the most common forms of deductive reasoning in science are the following:

- Deriving the hypothesis from theories and models, and
- Conceptual explications: when the meaning of a concept is clarified through the deductive derivation of its constructive meaning.

The Cape Peninsula University of Technology (CPUT) library databases 'Compendex Engineering Village' and 'EBSCOhost GreenFILE', were used to retrieve the appropriate journal and conference articles. Key words used were combinations of: 'Green building', 'measurement', 'sustainability', 'performance', 'indicator', 'criteria', and 'evaluation'. These articles were further refined by reviewing abstracts and conclusions as suggested by Kamali & Hewage (2015). The common Key Performance Indicators (KPIs) were prepared, modified, and combined to form the refined KPI set for each of the sustainability dimensions using the content analysis method. A broad definition of content analysis according to Holsti (1969) is "any technique for making inferences by objectively and systematically identifying specified characteristics of messages." All forms of documents, including electronic and printed, such as letters, books, survey reports, organisational papers, and advertisements, can be used as references.

2.1 Definitions and basic concepts

There are a number of key terms used in this paper and their definitions are as below.

Green building: is defined "as a construction project that is either certified under any recognised global green rating system or built to qualify for certification." (Bernstein & Mandyck, 2013: 5)

Performance evaluation: This refers to the process of assessing or evaluating the performance of the whole building or its component parts, according to a set of performance targets, criteria or requirements (Foliente & Tucker, 2007: 1).

Performance indicators: Performance indicators are a set of measures that reflect the environmental credentials or performance of a building. It should be noted that in research literature, a distinction is made between environmental or 'green' assessment and 'sustainable' assessment; the latter includes the indicators covered in the former and extends its scope to include social, economic, and other indicators (Foliente & Tucker, 2007: 1).

Performance criteria: This is an expression or statement of the level of performance an indicator is required to achieve. It includes two elements: (a) a performance indicator, and (b) an acceptable value or range of values and grades (e.g. 1 star to 5 stars). Performance criteria may be quantitative or qualitative, or mixed (Foliente &Tucker, 2007: 1).

Sustainability: The WCED, which is known as the Brundtland commission of 1987, defines sustainability as ''a process of change in which the exploitation of resources, the direction of investments, the orientation of technological development, and institutional changes are made consistent with future as well as present needs.'' (WCED, 1987)

3. Rationale for key performance indicators

Performance indicators are quantifiable performance measures used to define success factors and measure progress toward the achievement of stated goals. The measures are typically referred to as Key Performance Indicators (KPIs) and used within a balanced scorecard as a method of consolidations (Feifer, 2011). KPIs are metrics (financial and non-financial) that are used by organisations and individuals to check compliance with stated requirements or to define and measure progress towards stated goals or objectives (Lowe & Ponce, 2009). Consequently, a KPI can be described as a "key part of a measurable objective which is made up of a direction, a target, a benchmark, and timeframe" (Jones & White, 2008). Foliente & Tucker (2007) contend that occasionally, an assessment should be undertaken to check if the KPIs meet the performance targets set beforehand. In other cases, an assessment is done to obtain a snapshot of performance to which current and future facility improvement works can be compared (Foliente & Tucker, 2007). Lowe & Ponce (2009) affirm that the rationale for performance measure seeks to establish position and to monitor progress because organisations want to communicate performance to shareholders or costumers in order to stimulate interest. To Foliente & Tucker (2007), the objective may be to benchmark a particular building's performance intended or in service to others of similar type and / or size. Actual in-service performance matters most because impacts and consequences or benefits are real, it serves to validate design or refurbishment intent, and it contributes to knowledge and could improve future practice (Foliente & Tucker, 2007). Usually, KPIs are embedded within performance measurement and benchmarking systems (Lowe & Ponce, 2009). According to Newman & Jennings (2008), indicators are important in holding governments and communities accountable to their sustainability targets and goals. In addition, indicators provide data to guide policy-making and allow for comparisons to be made across local authorities, municipalities and provinces.

4. Identification and classification of performance indicators for green building

When identifying and defining key performance indicators for buildings three different performance levels can be distinguished, these are environmental performance, social performance as well as economic performance (Kamali & Hewage, 2015; Gibberd, 2011; Todd & Fowler, 2010). Traditionally, most green building rating systems have understandably tended to focus exclusively on environmental impacts. However, internationally within the green building movement there appears to be an increasing interest in the inclusion of social and economic impacts as well, and a shift in this direction (GBCSA-WGBC, 2013). Some researchers have argued that green building performance indicators should address two criteria (see Gibberd, 2011; Feifer, 2011), for instance Gibberd suggested environmental and building Criteria. Other researchers (see Ugwua & Haupt, 2007; Sham & Ma, 2013; Kamali & Hewage, 2015) have expressed contrasting view that green building performance indicators should address three criteria since the concept of sustainability usually spans three factors: social, economic and environmental. In recent years, building owners and designers, researchers, and academics have begun performing studies related to the costs and benefits of green design. Some of these studies attempt to address the full impact of green building designs, while others emphasise the economic aspects, the environmental impacts, and the social aspects separately (Todd & Fowler, 2010)

4.1 Economic performance indicators

In the context of developing countries such as South Africa, economic performance of green buildings is aimed at employment creation and economic opportunity. Employment creation is to encourage and recognise developments, which create employment opportunities through design decisions, and construction practices that include facilities for micro-enterprises, targeted employment for priority groups, and labour-intensive construction methodologies. More so, economic opportunity is aimed at encouraging the growth and development of small, micro and medium sized enterprises (SMMEs) through interventions during the design, construction and operational phases of a building, including procurement of goods and services, and enterprise development support programmes (GBCSA, 2014b). Naumann *et al.* (2011) express similar sentiment that economic performance indicators are aimed at creation of permanent jobs in maintenance of green infrastructure, benefits for businesses including contractors, tourism and leisure businesses, land and natural resource, based enterprises, and the creative industries. Feifer (2011) contend that economical dimension contains four general indicators, covering the cost of a building up front and seen over years, maintenance and costs for operations, suitability for conversions, and number of refurbishment cycles. Other studies revealed that economic indicators encompass two aspects. For instance Sham & Ma (2013) research show that the two indicators cover asset value and building maintenance. On the other hand, the work of Andrade & Bragança (2011) classified these two aspects as cost and bureaucracy.

4.2 Environmental performance indicators

To Boyer, Creech & Paas (2008), the goal of environmental performance indicators is to contribute to conservation and sustainable management of resources. There are three general indicators within the environmental dimension, limited to the assessment of environmental impacts and aspects of a building on the local, regional and global environment. The quantifiable indicators are expressed mainly as a lifecycle assessment and with some additional quantifiable environmental information (Feifer, 2011). Environmental criteria should include; energy, water, indoor environmental quality, land, materials, and transport. Building criteria includes; greenhouse gas emissions, lighting power densities, potable water consumption, ventilation rates, electric lighting levels, individual comfort control, daylight, topsoil, recycling, and public transport (Gibberd, 2011; Sustainable Cities International, 2012).

4.3 Social performance indicators

Social performance indicators is the least studied and least understood aspect of building performance since the parameters to be included in this category have not clearly defined. It is often challenging to measure the actual effects of a given building on social, community, and health indicators according to Todd & Fowler (2010). Social performance indicator is to provide income or employment to community beneficiaries and contribute to community livelihood and well-being (Boyer *et al.*, 2008), as well as social benefits through education, skills, volunteering, and community engagement (Naumann *et al.*, 2011). The social dimension covers five indicators, mainly the impacts of a building related to its occupants, expressed by quantifiable indicators (Feifer, 2011). These factors were clustered into three key priority themes: employment and economic opportunity, education and skills development, health and safety, equality and community engagement, and benefit (GBCSA-WGBC, 2013). For instance, education and training in new skills for green buildings can help to sustain existing economic activities more efficiently and effectively as well as diversify the economic base of communities (Boyer *et al.*, 2008). Because green building presents an opportunity to address some of the issues and problems that affect construction workers, such as the promotion for social dialogue in decision-making, providing equal access to opportunities and retraining of workers [International Labour Organisation (ILO, 2011)]. Improvements in community health and wellbeing that result from increased income, new skills and stronger community organisation can be signalled by more children attending school and improved access to health care.

Observing and documenting such changes for annual reflection will help triple bottom line enterprises ensure that the downstream social benefits are in fact being realised by their target beneficiaries (Boyer *et al.*, 2008).

However, in the South African context, the performance indicators are categorised into two main groups. The first one is the environmental aspect and the second is the amalgamation of the social and economic aspect to form socio-economic category. The key performance indicators are summarised in table 1

Table 1: A summary of the key performance indicators

Category	***Criteria***	***Performance Indicators***	**Key Reference**
Environmental	*Energy*	• *Lighting power densities*	*Gibberd (2011)* *GBCSA (2014a)* *Sham & Ma (2013)*
	Water	• *Potable water consumption*

5. Strategies to selecting and improving key performance indicators

A systematic selection and monitoring of performance indicators as well as evaluation of projects and policies based on a common methodology would be necessary to continuously improve the development of performance indicators in the South African built environment. The approach to selecting indicators generally falls into two general categories, top-down or bottom-up. The top-down approach means policy makers define the goals and accompanying indicators, the data collected is usually highly technical and requires experts to interpret (Sustainable Cities International, 2012). Therefore, Buys & Hurbissoon (2011) contend that tertiary institutions or other service providers should provide green building training opportunities for all built-environment stakeholders to take up the challenge in transforming the green building sector. The bottom-up approach is community-based and involves extensive consultation with stakeholders to select appropriate indicators. The key difference in the two approaches is complexity. Top-down processes involve more tools that allow for greater depth of analysis, while bottom-up processes are more basic and broad. It is possible to combine the approaches to create a hybrid approach; however this depends on the context. These two approaches reflect the need to develop indicators that are based on accurate scientific data as well as indicators that are easy to understand for the public and decision-makers. A solution to this problem that has been put forward is to select a set of 'core' indicators, which span the breadth of a community's sustainability goals. These core indicators should be easily understood and demonstrate the linkages between multiple sustainability goals (Sustainable Cities International, 2012). Thus adequate understanding and knowledge of KPIs is a desirable first step towards achieving the educational goals. It is also one of the main underpinnings for successful institutional transformations, and efficient decision making in design, specification and construction, at various project-level interfaces, using appropriate decision-support tools (Ugwua & Haupt, 2007).

The effectiveness of green performance guarantees in practice should be assessed, including the existing tools and technical monitoring systems (for water, energy and waste) that are applied (UNEP-SBCI, 2014). Through performance guarantees, developers / owners can address the risk of not achieving a stated indicator of green performance, such as a level of certification according to a green building rating tool or a specified energy performance with associated financial benefits. The most common performance guarantee addressing green or resource efficiency includes water and Energy Performance Guarantee (EPG) (UNEP-SBCI, 2014). However, in South Africa, the development and implementation of Energy Performance Certificates (EPCs) is at its infancy stage as a draft standard of the EPCs has been developed by a working group under the auspices of DPW and DoE (DPW, 2013). More so, Water Performance Certificates (WPCs) are not available in South Africa, but the Green Building Council of South Africa (GBCSA) has introduced a Water and Energy Benchmarking Tool which provides a basis for comparing a building's water usage to measured benchmarks. The Water and Energy Benchmarking Tool is however limited to office type buildings (DPW, 2013). Therefore the continued advancement of mandatory performance indicators for new buildings would serve as powerful incentives for change in the green building sector (Globe Advisors, 2012).

6. Conclusions

Significant research gaps still exist in terms of key performance indicators for green building in developing countries. The situation in developing countries such as South Africa clearly requires further implementation of policy measures as well as further research as many developing countries have not yet introduced or are just about to introduce policy instruments to enhance the development of key performance indicators for green buildings. The outlined literature indicates growing interest in research with respect to a three dimensional performance indicators for green building in both developed and developing countries. However, the socio - economic dimension is often difficult to assess either relying on subjective judgment or complex calculations which do not sit well in assessment systems that aim to be objective and time / cost effective to use. These challenges reflect the need to develop an all-inclusive indicators that are based on accurate scientific data as well as indicators that are easy to understand for the public and decision-makers. It should be noted that this paper is part of an on-going comprehensive research project currently being conducted by the authors regarding the critical factors that inhibit the growth of green building in the South African built environment in order to accelerate the understanding and implementation of green infrastructure in the country. Only very few evaluation studies are currently available and even fewer include quantitative data on effectiveness of green building performance indicators in South Africa. Therefore, the long-term objective of the research agenda is to conduct an empirical study to identify:

- How the public, decision makers and practitioners perceive the level of importance and the degree of utilisation of key performance indicators as related to green building?
- What progress has been made in implementing / enforcing these indicators in South Africa?
- What are the most significant challenges associated with the implementation of the indicators?
- The development of a method for identifying the impacts of socio - economic indicators on a green building construction and assessment.
- The need to be able to determine the level of performance and how it compares to a more typical building in the same climate, with the same occupancies.

- Measures on how the indicators can further be developed and how this can be introduced into the economy to improve sustainability in residential building.
- A framework for post occupancy evaluation for green buildings according to a set of performance targets, criteria or requirements.

Abstract

Various software tools have been developed to evaluate the life cycle performances of roads to provide decision supports for road authorities and contractors. It is therefore important to compare the strengths and limitations of these software tools to understand the appropriate application and to identify the points for optimization. This study evaluated EFFEKT 6.6, EKA, and LICCER software tools, by applying the environmental life cycle assessment following the ISO 14040 standard. The assessment was based on an open-air road (excluding tunnels and bridges) with a functional unit of one kilometer and greenhouse gas emissions as well as embodied energy indicators were evaluated in the considered software tools. The open-air road was modeled for each software tool with respects to road class H9 characteristic in Norway, classed as a national road. The assessment showed that the system boundary and purpose of use differed between the considered software tools. This resulted in performing the assessment only over A1 – 4 and B6 modules according to EN 15978 standard for the hypothetical open-air road to provide a comparable boundary condition. The results demonstrated that EFFEKT overall yielded higher values for greenhouse gas emissions and embodied energy compared to the two other software tools, while, the three software tools quantified nearly the same amount of asphalt use within the 20-year analysis period.

Key words: LCA, asphalt, GHG emissions, embodied energy, road

1. Introduction

Roads as part of the transport infrastructure contribute to job creation and growth of GDP. However, roads are also corresponding to natural resource use, land usage, emission and waste creation. And, every year new roads are built, maintained and rehabilitated due to an increased demand for new roads and deterioration of existing roads. This growth in demand and increase in cumbersome issues (like availability of resources, environmental awareness etc.) puts decision-makers in a challenging position to address and comply with the various challenges.

Environmental life cycle assessment (LCA) is a well-established and standardized method and has been widely used due to the increased awareness in importance of environmental stewardship (ISO, 2006). LCA is a method that evaluates potential environmental impacts for a product or service over its full life cycle (ISO, 2006). And so far, different LCA studies have been conducted in the area of road infrastructure in order to better understand the environmental impacts associated with roads and road products such as ECORCE2, DuboCalc, PaLATE, SEVE, etc. (Zukowska E. A. et al., 2014). In spite of availability of different road LCA software tools (Hammervold, 2014), different areas of coverage could be found in the domain of software that might be due to various system boundaries and intended applications. This leads to the fact that some LCA software tools may show unexpected results.

The present work is aiming to evaluate three currently used software tools based on a hypothetical Norwegian road, especially regarding the results achieved in terms of embodied energy and greenhouse gas emissions. The considered software tools are EFFEKT 6.6[1], EKA[2] and LICCER[3]. The hypothetical road is chosen from manual 017 "Road and street design" (NPRA, 2013b) and categorized as road class H9 with a total distance of one kilometer with annual daily traffic above 15 000 vehicles.

2. Methodology

Environmental Life cycle assessment (LCA) is a well stablished method and has been widely used due to the increased awareness of importance of environmental stewardship (ISO, 2006). LCA is a methodology that analyzes and evaluates the environmental impacts associated with a product system, service or activity in a systematic way through its entire life cycle (Baumann and Tillman, 2004, Lindfors et al., 1995, ISO, 2006). The entire life cycle or "cradle-to-grave" refers to the whole value-chain of a product that can be simply comprised of extraction, manufacturing, transportation, use, and disposal activities. These stages are explicitly illustrated by EN 15978 standard in figure 1.

---

[1] http://www.vegvesen.no/
[2] http://www.trafikverket.se/
[3] http://www.eranetroad.org/

LCA is often performed to compare different product systems with a same functional unit, to find critical stages and/or processes (hot spots), or to document environmental performances as internal reports (Robèrt K. H. et al., 2002, Baumann and Tillman, 2004).

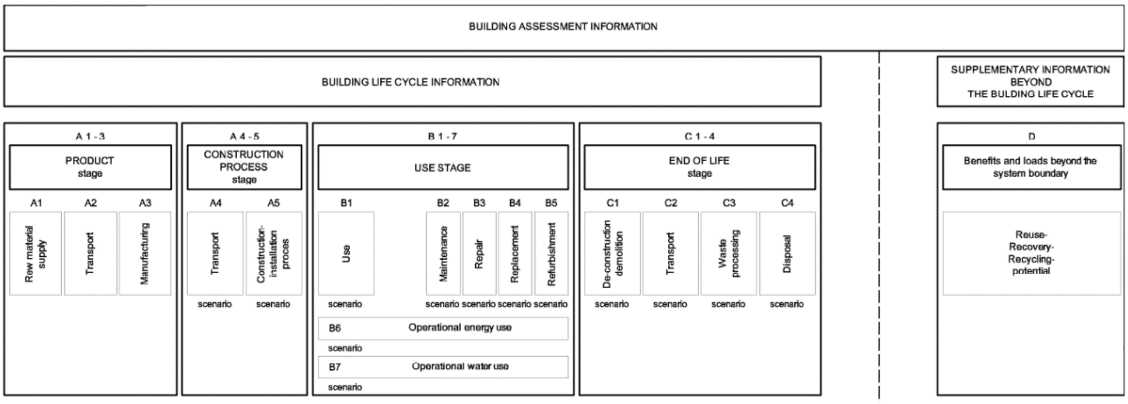

Figure 1: Modular information for building life cycles (CEN, 2011).

Based on a description that has been provided by International Organization for Standardization (ISO) within ISO 14040:2006 standard (ISO, 2006), a LCA is comprised of four main stages: goal and scope, inventory analysis, life cycle impact assessment, and interpretation (see figure 2) (ISO, 2006).

- Goal and scope describes what the target, purpose, and relevant choices are.
- Inventory analysis identifies input/output material, energy, and corresponding emissions.
- Life cycle impact assessment measures the potential impacts from the developed inventory in a qualitative way.
- Interpretation explains the results in each stage to increase the transparency and to help make more informed decisions.

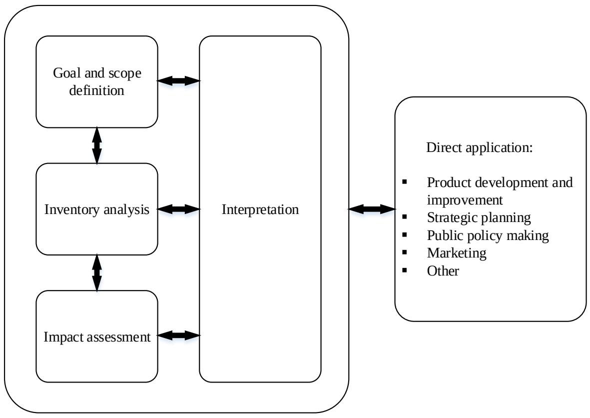

Figure 2: Four stages of an LCA (ISO, 2006)

3. LCA tool

The three software tools, which are in the scope of assessment of this paper, are EFFEKT6.6, LICCER and EKA. Here, a brief description for each software tool is provided to represent the focus area of the LCA tools.

3.1 EFFEKT 6.6

EFFEKT is a software program that is developed by the Norwegian Public Road Administration (NPRA) (Hammervold, 2014). It is a tool that assesses cost-benefit and socio-economic analyses of road infrastructures. EFFEKT is particularly developed for and regularly used during early stages of road infrastructure planning (Miliutenko S. et al., 2014a), aiming at roughly estimating the consumption of inputs, cumulative energy use and GHG emissions in a context when little data for a new road project are actually available. EFFEKT is carried out to assess the impacts from alternative routes of a road projects compared with a reference scenario (baseline) that helps for selection of solutions or prioritization of route alternatives within a road project (NPRA, 2007, Martinsen J. A., 2008). EFFEKT includes *production*, *construction* and some modules of *use* life cycle stages as shown in figure 1, but it excludes *end-of-life* and *potential benefits and loads* life cycle stages from its assessment (Liljenström, 2013). The main focus of the calculations is on impacts from major material production activities and selected construction activities.

3.2 EKA

EKA was developed by the Swedish Transport Administration to calculate inputs, cumulative energy and GHG emissions of different road maintenance activities for various asphalt types (Martinsson, 2014). The tool covers the entire asphalt production value chain (from input materials to the finished products) based on Swedish production techniques. This means EKA incorporates submodules A1 – 4, and also, it covers some parts of *use, end-of-life* and *potential benefits and loads* life cycle stages in its assessment. The final asphalt products in EKA tool are: hot mix asphalt, warm mix asphalt, half-warm mix asphalt, remixing (recycled asphalt), tank coating (surface treatment), and thin-layer coating (Martinsson, 2014).

3.3 LICCER

LICCER was a research project funded by ERA-NET with the aim at developing “an easy to use model based on existing tools and methodologies for Life Cycle Assessment of road infrastructure” (Brattebø H. et al., 2013). LICCER was to a certain extent motivated by EFFEKT and it evaluates inputs, GHG-emissions (in ton CO_2-eq/year) and cumulative energy demand (energy use in GJ/year) in early planning of road infrastructure (open-air roads, bridges, and tunnels), as well as road furniture (O'Born R. et al., 2013, Brattebø H. et al., 2013, Liljenström, 2013, Miliutenko S. et al., 2014b, O'Born R. et al., 2015). LICCER includes *production*, *construction* and some modules of *use* as well as *end-of-life* stages, but it excludes *potential benefits and loads* life cycle stage from its assessment.

4. Case study

Manual 017 (NPRA, 2013b) entitled “Road and Street Design” was a guideline used in this study. The manual developed by the Norwegian public road administration (NPRA) provides technical requirements for the design of roads and streets and it does not discusses non-traffic related conditions (like landscape condition, geology, etc.) (NPRA, 2013b).

Based on the manual 017 (NPRA, 2013b), there are various road classes for construction of national main roads. Here, road class H9 is selected for the assessment, which is classed as the national main road. The road class H9 has a motorway standard with the speed limits of 100 km/h. The road must be built as a 4-lane road with driving lane and hard-shoulder of 3.5 and 3 meters wide, respectively, and it consists of a 23 meter wide roadway in total (NPRA, 2013b). Figure 3 illustrates the schematic view of the road cross-section.

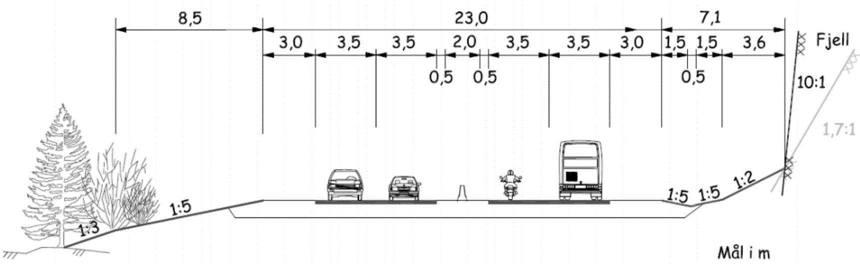

Figure 3: The cross section of national main road H9 (NPRA, 2013a)

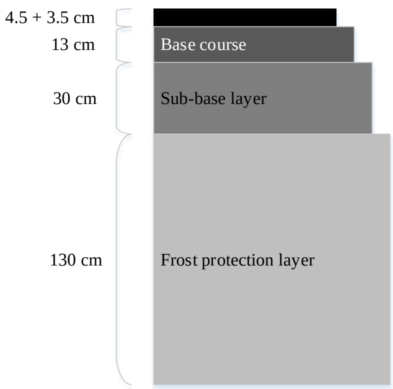
Due to the fact that there was no reference model for a typical pavement structure corresponding to design class H9, it was necessary to design a hypothetical road first in order to assess the environmental impacts from the road in a next step. To do so, empirical pavement design is selected based on chapter 51 in the manual N200 (NPRA, 2014). By means of manual N200, it is possible to design an empirical road pavement with some prerequisite input data such as subgrade condition, traffic load, road construction materials, climate condition and standard structure.

Table 1: The structure of designed pavement for road class H9

Layer	*Material type / thickness*
Wearing course	*4.5 cm asphalt concrete*
Binder course	*3.5 cm asphalt concrete*
Base course	*13 cm asphalted gravel*
Sub-base	*30 cm crushed rock*
Frost protection	*130 cm crushed rock*
Total thickness	*181 cm*



In the designing stage of a hypothetical road pavement, it is assumed that the road is located in Malvik municipality. The ADT in the opening year is assumed to be 15 000 vehicles[4] (with 12% share of heavy vehicles) and it is assumed that annual heavy vehicles traffic growth is 1.4%. The frost amount F100 is 18 000 h°C (it is assumed that the maximum correction factor is 1.3; annual mean temperature is 5.4°C and average frost amount F_{100} is 18 000 h°C) and road subgrade

[4] Annual daily traffic (ADT) above 20 000 vehicles is suggested for the road class H9 (according to manual 017); however from a hypothetical viewpoint in this paper, it is assumed the road provides service to ADT above 15 000 vehicles in its initial operation year.

consists of clay with Cu T4. Table 1 presents a theoretical pavement layers that designed for the hypothetical road.

5. Results

Although the introduced software tools have intentions to quantify GHG emissions and embodied energy associated with road projects, they slightly differ where they draw their system boundaries. EFFEKT 6.6 on the one hand covers production, construction and (some modules of) use stages (B1, B2 and B6) in its system boundary. And, LICCER covers more life cycle stages compare to EFFEKT 6.6 by including production (A1 – 3), construction (A4 – 5), use (B1, B2 and B6) and end-of-life (C1 – 3) phases. EKA on the other hand has a more limited coverage. EKA does not consider construction phase of a new road (stage A5) like earthworks, drainage system, unbound layers etc. in its assessments. Instead, it only evaluates embodied energy and GHG emissions associated with bound layer products within maintenance activities.

With respect to the described dissimilarities between the LCA software tools, it became clear that performing a full lifecycle “cradle-to-grave” was not applicable due to limitation in the system boundary of the EKA tool and not full lifecycle coverage by EFFEK 6.6 (as it is explained in EN 15978 standard (CEN, 2011)). Thus, in order to run a fare comparison between these three software tools, it has been decided to evaluate them based on the *stages* and the *modules* that they have in common. By doing so, it could be said that the maintenance module from the *use* stage (B2) as well as A1 – 4 modules are mutually covered by these three software tools (see figure 4).

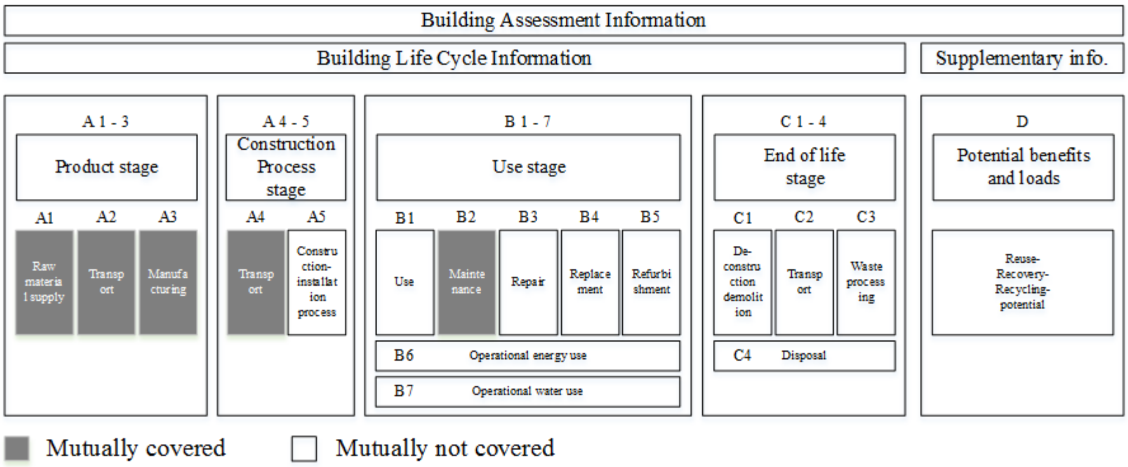


Figure 4: Life cycle stages and modules shared mutually between the three software tools.

EFFEKT 6.6 in general does not require any calculations regarding the amount of material inputs for the maintenance of a road. Instead, it only demands information on the length, number of lanes, layer thicknesses, widths, traffic volume etc. that were all described in the case study of this paper (see chapter 4). LICCER in this regard inquires inputs similar to the EFFEKT tool, but as an alternative the user can insert project-specification data in LICCER if such data are available. Nonetheless, the condition is different for EKA. EKA needs more detailed data (like, production rate, tons and corresponding thickness of materials etc.) to calculate the GHG emissions and embodied energy. Therefore, in order to quantify the masses of input data for each maintenance activity, the following equation is conducted to quantify tonnage of asphalt pavement.

$$AS[ton] = (\mathrm{T} \times \mathrm{L} \times \mathrm{B} \times 2.5) \quad (1)$$

In formula (1), AS is the total tonnage of asphalt wearing course; T is the thickness of wearing course; L is the length of road; B is the width of road; and 2.5 (ton/m^3) is material density of asphalt.

Formula (1) is the same equation that is introduced by EFFEKT 6.6 in its manual (Straume A. and Bertelsen D., 2015) to calculate the amount of an asphalt wearing course. LICCER also proposes almost a similar formula, the only difference is the asphalt density. LICCER considers a density of 2.24 ton/m^3 as a default for asphalt product, instead of 2.5 ton/m^3 in EFFEKT[5]. Whereas both tools assume that a typical hot mix asphalt (corresponding to 96% of production of asphalt product in Norway) consists of 94% aggregates and 6% bitumen.

As many roads are designed based on certain standards to fulfil the pavement serviceability, various influential parameters influence the maintenance intervals (like traffic volume, climatic zone, subgrade strength, frost depth etc.) over years (Garbarino E. et al., 2014). In this paper, maintenance intervals are taken from report no. 358 (Straume A. and Bertelsen D., 2015) that suggests pavement lifetimes with respect to different traffic volume. It is also assumed in each maintenance activity, 0.04 meter of road is milled and replaced by new asphalt wearing course.

By inserting all the input values to the three LCA software tools, the following results can be observed (table 2):

Table 2: Results of the Norwegian hypothetical national road within a 20-year analysis period with three LCA tools.

	EFFEKT 6.6	*EKA*	*LICCER*
Greenhouse gas emissions (ton CO_2.eq)	*487*	*344*	*296*
Embodied energy (GJ)	*28 108*	*5 786*	*27 400*
Amount of re-asphalting (ton)	*8 330*	*8 400*	*7 526*

6. Discussion

With respect to table 2, it became clear that the application of three different LCA tools to compare the hypothetical Norwegian national road (over a considered period of 20 years), led to different absolute and sometimes conflicting results. EFFEKT 6.6 showed higher GHG emissions compared to EKA and LICCER. However, by comparing embodied energy and asphalt, LICCER

[5] As a simple solution to calculate asphalt consumption, it is proposed by NPRA that 1 cm of asphalt has approximately 25 weight per square meter (kg/m^2) (NPRA, 2005).

and EFFEKT 6.6 showed a close similarity in their results. Also, EKA and EFFEKT showed the amount of consumed asphalt with only small differences (less than 1%). Due to the differences in absolute numbers gained by the application of the three LCA tools, the main drivers need to be identified

A more in detail analysis reveals that the level of details in data compilation and assessment were not the same in the software tools. EFFEKT showed its results in an integrated approach to indicate GHG emissions and energy as well as materials consumption (might be due to this fact that EFFEKT is intended to have a more informative way to communicate its results). Such a limitation in EFFEKT is because of high level of aggregation that makes it hard to see what the attribution of different attributors are for each material. For instance, a typical asphalt pavement consists of different input materials (like aggregates, bitumen and other additives) that have different transportation patterns and corresponding embodied energy, which in EFFEKT all attributors are aggregated and shown as one representative attribute. Nevertheless, LICCER and EKA showed an advantage over EFFEKT 6.6 due to giving a possibility to their users to go through different spreadsheets in their software tools in favour of finding the reference assumptions.

Concerning the illustrated disparity in the magnitude of the results (table 2), a possibility to do calculations manually would be seen as a large benefit. Equation 1 represents how the tonnage of asphalt wearing course can be quantified for all the three software tools. By replacing variables with their representative values, the tonnage of asphalt pavement during each maintenance activity can be quantified. The results from the calculation showed that LICCER and EKA quantify 1881 and 2100 tons of asphalt pavement are consumed in each maintenance cycle, respectively. The results demonstrate (if the maintenance activities are happening 4 times in the period of 20 years) that the numbers are aligned with the results shown from LICCER and EKA in table 2.

However, the calculation of consumed asphalt for EFFEKT was not straight forward because it is based on cost principles in its analysis. This means EFFEKT considers a yearly cost for every year in the analysis period due to expected future maintenance activities, which might be based on expert opinions. In the road example taken in this paper, EFFEKT calculated two different maintenance cycles through the analysis period of 20 years. It considered one-sixth of maintenance in the first maintenance cycle[6] that would be attributed to the first year after construction of the road. However, in the remaining years (from the 2nd year till the 20th year), EFFEKT considered the maintenance activity would happen every other fifth year over the following 19 years (Kroksæter A., 2015).

$$Year\ 1: ((0.04 \times 1000 \times 21 \times 2.5))/6$$

$$Year\ 2\ -\ 20: ((0.04 \times 1000 \times 21 \times 2.5))/5 \times 19$$

[6] This mean that the first maintenance cycle is taking place after six years.

In the above formulas, 0.04 is the thickness of wearing course; 1000 is the length of road; 21 is the width of road; 2.5 (ton/m^3) is material density of asphalt; 5 and 6 are maintenance cycles after five years and six years, respectively; and 19 is the number of years between year 2 and year 20.

One reason that LICCER shows a lower value in GHG emissions is because of the lower asphalt concrete density that is assumed in the section of material specification. In EKA and EFFEKT, the density of asphalt concrete is assumed to be 2.5 ton/m^3; however, LICCER considers asphalt density of 2.24 ton/m^3 as its default value. By only adding 0.26 to the presumed asphalt concrete density in LICCER tool, i.e. assuming the asphalt concrete is 2.5 ton/ m^3, the amount of bitumen consumption in each maintenance activity increases from 112.9 tons to 126 ton. This alteration in the amount of bitumen usage can correspond to additional 5.63 ton CO_2.eq. In addition, LICCER considers 5.99 kg CO_2.eq/ton corresponding to asphalt mixing plant in its assessment, which has the lower ratio compare to the other software tools. EKA considers approx. 21 kg CO_2.eq/ton for asphalt mixing plant, while, EFFEKT only shows one aggregated number (58.5 kg CO_2.eq/ton) for 'asphalt' that consists of GHG emissions from material extraction to placement on the road.

EKA showed a disproportional embodied energy compared to the two other software tools within the analysis period of 20 years. One of the rationales for such a deviation in the result is due to differences between values of bitumen embodied energy. EKA considers energy value of 720 kWh/ton (2.59 GJ/ton) for bitumen, but LICCER considers 52 GJ/ton (almost 20 times greater). This inconsistency in the result for the embodied energy of bitumen might be due to dissimilarity in the boundary of bitumen values chain. If we compare the results more in depth, it can be said that bitumen corresponded to approx. 85% of energy consumption in LICCER, but bitumen only had approx. 20% of contribution in EKA embodied energy. Furthermore, the results were compared with ecoinvent version 3.01 'Pitch' production process[7] (ecoinvent Center, 2013). The process by means of CML V4.01 impact assessment method showed the embodied energy is approx. 51 GJ/ton for bitumen production at the refinery. Given results and comparison with ecoinvent value show that the calculation done by LICCER is aligned with ecoinvent assessment. However, one should be consider is that the result in addition to data input consists in methodology of choice because the result may differ if another methodology is chosen. It is hence very important to carefully control for this dissimilarity via a systematic approach (as it is explained in the European Standard 15804:2012+A1 (CEN, 2013)) to reduce any miscalculation and successive misperception of results.

It became obvious that the three LCA tools have a focus only on greenhouse gas emissions and resource consumption, which raises the question why other environmental metrics (impact categories) are not considered. In fact, having a shorter list of impact categories makes the interpretation of LCA results easier for decision-makers, as it is all about comparing different product systems with a same functional unit. However, taking decisions on only a few LCA indicators carries multiple risks. In addition, it was not clear (except for EKA[8]), how the greenhouse gas emissions have been calculated in terms of considered greenhouse gases and

---

[7] Pitch (Europe without Switzerland) | petroleum refinery operation | Alloc Def, U.
[8] EKA includes solitary three climate gases in its greenhouse gas emissions that are: CO_2, CH_4 and N_2O.

impact factors. Due to this fact that Kyoto Protocol only covers six greenhouse gases in its first commitment period, which results in excluding short lived climate gases (e.g. black carbon) from its target. In fact, these short lived climate gases cause approx. 60% of overall global forcing (Rhodes S. P. and Schultz T., 2014). Hence, this is essential to be aware of climate gases that are not included in the assessment of GHG emissions, as they may have significant influence in the overall results.

Although this study by means of the three LCA software tools showed a range of results, it was essential to compare the results (from this study) with an Environmental Product Declaration (EPD) report (Nielssen C. S. and A., 2011) to evaluate the magnitude of similarities. The report showed that production and placement of asphalted gravel concrete (Agb 11) contributes to 56 kg CO_2.eq and 1141 MJ per ton of asphalt pavement. By scaling up the result of the EPD based on the assumptions given earlier in this paper, the greenhouse gas emissions from the asphalt manufacturing in the 20-year period sums up to approximately 470 tons of CO_2.eq, which shows roughly similar to what has been shown by EFFEKT 6.6 tool. However, the result of embodied energy shows 9584 GJ during the same time period, which is not aligned with the results of the three software tools in this study. The reasoning of having similarity or dissimilar results for the embodied energy and the GHG emissions has not been possible to be farther assessed. Due to the fact that the EPD report used another way of demonstrating the results, which made it impossible to compare the values with the other software tools.

7. Conclusions

To conclude, it can be stated that LCA needs a critical review in order to diagnosis any possible hidden errors in life cycle inventory and LCA results. Given the fact that a small error can accumulate through the life cycle assessment and consequence a substantial error in the overall results. This study was performed with the intention to evaluate three LCA software tools (EFFEKT 6.6, LICCER and EKA) to magnify the area of their coverage, strength and limitation of each software tool.

This paper assessed the software tools by comparing the results for a hypothetical road. The assessment covered resource consumption and greenhouse gas emissions as its proxy and considered road class H9 as it is hypothetical road. Although the supporting tools were intending to assess environmental performance of road projects, they had dissimilarities in their system boundary conditions. Therefore, the system boundaries for assessment were narrowed down to the maintenance phase within a 20-year analysis period.

In spite of the fact that the assessed tools addressed GHG emissions and embodied energy, there was no consistency in the results. These variations in the magnitude of results may lead to decisions on false grounds when it comes to making a comparison between different road options for decision makers. Therefore, having a transparent scope in LCA and explicit documentation make it possible for readers and future decision-makers to have a better insight into and therefore make more informed decisions based on LCA analysis. In addition, limitations and recommendations are additional pieces of information that need to be delivered at the end of LCA works to declare and highlight the accuracy level for the intended users and readers.

It will be necessary that future LCA software tools integrate more details and additional data into their inventories in favor of making the LCA results more comprehensive and transparent. In addition, it would be beneficial to consider the pavement-vehicle interaction and the effect on energy consumption due to rolling resistance and geometry of roads as well. Winter service and effect of it on winter maintenance strategies, especially in cold climatic zones, can bring more dimensions to the scope of assessment. Including more environmental impact categories and using comprehensive database as well as impact assessment methods are very critical and need to be carefully handle in order to provide more thorough and fair environmental impact assessment. End-of-life material policy should include more than material transport after maintenance activities. It should cover more data like; amount of waste asphalt generated and stored in storage sites, maximum permissible storage time of waste asphalt in depots, etc.

Abstract

This paper describes development of a methodology to support better retrofit and maintenance with optimised energy consumption using evolving technologies in material, components and systems both at building and neighbourhood levels. It is based on a retrofit and maintenance scenario focused on specification of the functional requirements, databases requirement and system architecture for the construction and operation of the decision support tool. Decision support (DS) tools have already been developed for architects and building designers to choose best building design options with retrofit and maintenance in mind. However, there is a lack of understanding of the required data structures, databases, definition of the functional requirements and the variety of the possible system architectures for this application. The proposed DS tool will support Facility Management (FM) to design their option on Building Information Model (BIM) file by making best retrofit and maintenance decisions for improved energy efficiency (EE) without needing full knowledge of the latest technologies in any required subject and without being expert in building energy performance analysis and simulation. A detailed retrofit and maintenance scenario and its corresponding process map are developed and explained in details. Database requirements are extracted and discussed, leading to specification of the necessary structure and content with a level of details. The functional requirements for retrofit and maintenance design scenario are discussed and an exhaustive list is generated. The decision support tool was structured using four building blocks: (i) energy performance and simulation block; (ii) retrofit and maintenance options generator; (iii) optimisation block and; (iv) a decision making block based on Multiple Criteria Decision Making (MCDM) method.

Keywords: Decision Support, BIM, Building Energy Performance, Retrofit and Maintenance.

1. Introduction

This paper describes functional requirements and system architecture for decision support of energy efficient (EE) building design in retrofit and maintenance stage. Decision support (DS) tools are becoming more and more necessary for architects and building designers to make best energy efficient (EE) design decision, and support retrofit and maintenance projects (Ferreira et al., 2013). However, little has been done to identify the databases requirements to enable EE design that does support FM during operations. This paper draws the stages of the process for design of a decision support system including its required databases and decision making criteria. Functional requirements and system architecture are also elaborated in details toward development of the proposed DS tool. This is aimed to support facility management (FM) to design their maintenance or retrofit option on building information model (BIM) file through making best decisions for improved energy efficiency (EE) without being experts in the latest technologies of the required subject or being experts in building energy performance analysis and simulation. The necessary tools' architecture includes the alternatives generator tool, the energy performance assessment tool and the DS tool.

In order to achieve sustainable development of our society, retrofitting existing buildings to improve their energy efficiency has become an inevitable task for the government of several countries (DOE, 2009), (Green Deal, UK GOV), (CBRE, Retrofitting Existing Buildings). Generally, a sustainable building retrofit programme consists of five key phases, from the project setup and pre-retrofit survey phase to the validation and verification phase (Ma, 2012). In this process, identification of retrofit options using reliable data is essential for a successful building retrofit project. To provide reliable evidence for selecting suitable retrofit measures, dynamic building performance simulation tools, such as TRNSYS (Santamouris, 2007), EnergyPlus (Chidiac, 2011), (Wei, 2014), (Ascione, 2011), IES VE (Ben, 2014) and DOE-2 (Zmeureanu, 1990), have been used widely in real projects. Design4Energy (D4E) is an on-going EU research project, consisting of 17 partners from several countries in Europe, such as Spain, UK and Germany (Design4Energy). The project is aiming to develop an innovative Integrated Evolutionary Design Methodology, which can allow the stakeholders to predict the current and future energy efficiency of buildings and make better informed decision in optimizing the energy performance during the building life cycle. The work presented here is particularly focused on retrofit and maintenance stages. Within D4E a novel decision support tool based on dynamic building performance simulation therefore is being developed, and it meant to first be usable for building retrofit and maintenance projects to help stakeholders choose the most suitable retrofit/maintenance measure(s) for their projects (Fouchal, 2014).

The main decision making process focuses on using building simulation to predict the effectiveness of various retrofit or maintenance measures (alternatives) and inform the current development of a dedicated decision support tool for FM. Also the system relies in particular on adequate definition of database requirements in terms of components, parameters and indicators to automatically generate all possible retrofit or maintenance options. A set of databases are being developed for the decision support tool, this development includes identification of the requirements for IT systems, components, energy systems and, materials. Analysing existing database solutions was the first pre-requisite, then identification of databases' characteristics using focus groups of potential users (architects, energy designers and FM) and finally tuned to suite the type of decision support tool being developed. Decision support tools have been key in the providing smartens of many design platforms for building practitioners, the system architecture in question here is the main engine of the Design4Energy (D4E) platform (D4E, web1). These platforms do provide basis for collaboration and knowledge sharing with updatable databases. The value of design platforms is in their workflow speed and quality, facilitating team contribution integration, and rapid feedback on energy performance (NREL's OpenStudio, June 2015). OpenStudio started as an open source project to create a collection of software tools for energy modelling. For these platforms databases is essential for their functioning. While xBIM is another open source development platform, which allows creating application for BIM based on the IFC standard (xBIM, June 2015). TNO BIM Server is another open source development platform, which allows creating application for BIM based on the IFC standard (bimserver, June 2015). The Building SMART Data Dictionary (bSDD) is a reference library or a framework that aims at supporting improved interoperability in the building and construction industry. It can connect software applications to product databases or attach specific attributes to construction designs. These references can include information from a product manufacturer, typical room requirements, cost data or environmental data (ifd standards, June 2015), (ifd-library, June 2015).

Multiple Criteria Decision Making (MCDM) integrates multiple indicators into a single meaningful index to allow ranking and comparing options for decision making, see figure 1 (Fouchal, 2015). It is an efficient statistical method to combine component indices arising from all the information sources into a single overall meaningful index, therefore ranking and comparing are feasible. MCDM has the ability to weight different alternatives and make judgement on various criteria for possible selection of the best/suitable alternative(s). A typical MCDM problem is when there are a number of criteria to assess a list of alternatives. Each alternative is represented by a single value for each of the criteria to permit the assessment and/or ranking, see figure 1. Complex decision requires consideration of multiple criteria (Zeleny, 1982).

Analytic Hierarchy Process (AHP) method as proposed by Saaty (1994) that is based on priority theory decomposes a complex multi-dimensional decision making problem into a system of hierarchies. It uses the relative importance of the alternatives in terms of each criterion. The AHP has the ability to logically incorporate data and expert's judgement in the model for measurement and prioritising intangibles. As a complex and unstructured situation is broken down, its components are arranged into a hierarchic order including criteria and alternatives.

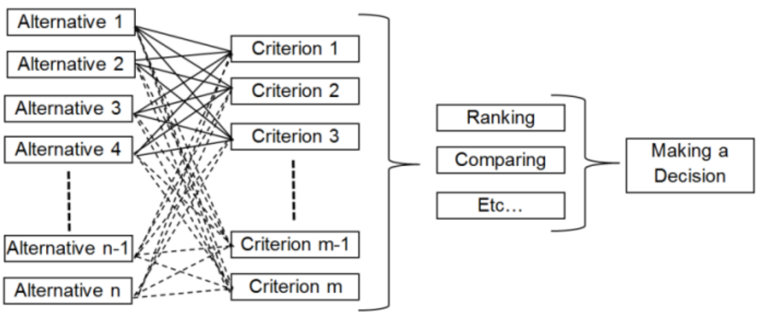

Figure 1 Multi criteria decision making (MCDM) process being adopted in D4E

Component catalogues relational databases are accessible through internet protocols. The Building Component Library (BCL) by NREL provides searchable information about EE related technologies and a list of measures to meet energetic issues (Fleming et al., 2012). The included information can represent physical characteristics of buildings such as windows, walls, and doors, or can refer to related operational information such as occupancy, equipment schedules and weather information. Each measure and energy system can be downloaded as a XML, RB and OSM file describing these components (bcl.nrel, June 2015). Data Repository ISES is another cloud-based data repository. It contains information such as climate data or stochastic templates but most interestingly energy product and material catalogues containing energy properties of products and materials (ISES D4.1, 2014). The library uses the PLIB ontology model (based on ISO 13584). All information is saved in the ifc file format (ISES D4.3, 2014). The MagiCAD Product Database is a product catalogue or database that contains over one million products from over hundred manufacturers. A designer can choose components through a plugin directly via the CAD-tool interface. This interface is connected to a plugin on the manufacturers' site (MagiCAD, 2014).

In the following sections are presented the retrofit and maintenance scenario, the process map, the functional requirement and database requirement to finally develop the system architecture for the decision support tool.

2. Retrofit and maintenance scenario

A detailed retrofit and maintenance scenario is developed and described here; the corresponding process map is also developed and explained in details in the section to follow. The scenario starts with the facility manager evaluating the operation stage and maintenance data of an existing building and reveals some building performance changes which require serious attention such as undertaking some repair or upgrade to the building. An architect takes over and starts analysing historical data of operation, maintenance records as well as user behaviour data, monitoring data, the map of neighbourhood energy nodes and cost data. From this analysis it becomes apparent that some of the data is not compatible with building's energy anticipated performance. He/she therefore request a thorough investigation of the causes of the energy consumption mismatch with original design in specific parts of the building which involves the heating system (Wei, 2015). A heating system expert is called in and identifies an old boiler as the source of the problem. The architect in collaboration with a building services engineer sketch a retrofit or maintenance design using a BIM model on the D4E platform. In doing so, the architect takes into consideration a number of parameters such as the local weather profile, facility management reports, financial status of the building owner and looks into other case studies to decide the best option forward for optimisation of energy level ahead of the conceptual design completion. At this stage, the architect considers the market and the various options for the energy performance of the project's life cycle and cost of future operation and maintenance to prepare to discusses various design options with the client to make a decision.

Mainly two routes become possible depending on the budget in hand and existence of information on new source of district heating to become available in the near future within the vicinity of the building. These options are analysed and evaluated by the designer comparing the retrofitting improvements versus maintenance action. The D4E platform supports the designers by highlighting critical building zones. The designer can filter out the existing building data for transferring them to certain design tools (CAD, etc.). Using the different design tools the designers can develop retrofitting variants for further integration and analysis in the collaborative platform. The simulation tool integrated in the system enables running a number of analyses to assess the impacts of the proposed retrofitting or maintenance variants on the energy efficiency and compare them to historical data of similar existing buildings. The design is then passed on to the mechanical and electrical engineers as a BIM model. The 3D collaborative environment provides them the possibility to explore what-if-scenarios, they can drag components from the database library to modify and optimise the design. Furthermore the platform provides them with cost estimation of the different options on different terms (short to long). The information required during these activities will be stored into a common database.

3. Process map

During the operation of the building the stages described in figure 2 are followed. The process of identifying building issues during the operation phase are described, where the building's under-performance is identified and adequate measures are undertaken through D4E platform.

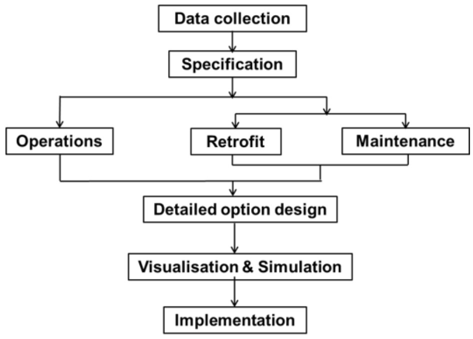

Figure 2 operation of the building including retrofit or maintenance

However, the process map being developed has no specific focus in terms of the type of the building requiring retrofit and maintenance. It is developed on a higher level and aims to cover all possible requirements of domestic and non-domestic buildings. However, in the case of industrial and buildings with specific uses (e.g. health care centres) adjustments would be required for the process map to be applicable, including the need for appropriate population of the databases with relevant information. For the purposes of this research, to verify the retrofit and maintenance process proposed and to validate the decision support tool, a case study of 20 domestic buildings is used. The main limitations and potential of the developed tool are highlighted. Additional testing of the decision support tool would be required to further validate its applicability in different types of buildings.

3.1 Monitoring building operation (client & FM):

During the operation stage of a building the client (user/owner) and the facility management team undertake scheduled monitoring and/or observation of the building performance, generally using electronic monitoring devices such as energy meters, which measure the energy consumption and store it periodically into a file using common format such as Excel. The operational monitoring data are produced in the form of sensor data (of energy systems, of energy used by equipment, user behaviour, indoor air quality and moisture level), operation bills (of energy/utilities) and maintenance/repair bills. The client gets signals from daily use and observation of the building behaviour in terms of indoor air quality (e.g. thermal environment, visual environment and acoustic environment), sensors/energy monitoring data and operational cost. If the building's indoor air quality level and moisture level have changed it may suggest that the building envelope or the energy systems have changed in a way that is not expected. Furthermore if the operational cost such as the energy bill has changed similar cause may apply. Under this kind of circumstances the client reports any observations to the facility management team. Similarly the FM team can make similar observations from the available monitoring data or studying reports from the client (written, emails or verbal), see figure 3. The data collected can be clustered as: (i) Building survey; (ii) Sensors and monitoring data; (iii) Client report & user interview; (iv) Review of maintenance strategy; (v) Access BIM files / As built drawings.

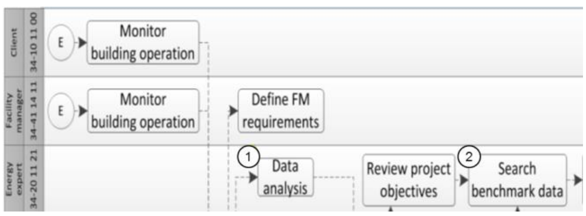

Figure 3 defining the need for retrofit or maintenance

3.2 Requirement, data analysis and review of project's objectives

Based on operation data the facility manager defines their requirement to re-establish the normal operation of the building or to upgrade the performance level for example to comply with new regulations or simply respond to the client request. The energy expert and other energy system experts such as HVAC engineers will use Tool 1 to assess the reported building energy performance issue and set targets for remedy or upgrade. The target setting will involve selection of key indicators and defining the operating ranges for each indicator. The energy expert reviews the objectives traced to meet the use and operation needs, these are identified on the basis of the FM requirements and the expected energy performance of the building.

3.3 Search benchmarks and finalise key target setting

The benchmark browser and search tool will be used to set the benchmarking related targets. The standard methods and benchmarks for consideration in this project include CIBSE (Chartered Institute for Building Services Engineers) TM22, TM46, TM39, TM46 and TM 47, the AM11 Building Energy and Environmental Modelling (BEEM) (CIBSE Applications Manual 11) and the EPBD (Energy Performance of Buildings Directive), IPMVP (International Performance Measurement and Verification Protocol) in the USA, as well as the Performance Contracting Program standards ISO. Setting key target levels will be based on benchmarks and client requirements by setting the range extreme boundaries for each indicator being.

3.4 Retrofit or maintenance options generation and selection

Choosing of energy options, then run a feasibility study and produce a feasibility report for retrofit and maintenance will be carried out by the energy expert first through selecting variables to be used to form the options, see figure 4. These variables will be displayed to him/her under a list of drop down menus providing all possible and available variants of each component or action to incorporate of performed. This process will be possible by manual generation of options by the energy expert using a set of integration parameters which help to combine the variables in various ways to produce a list of possible options with potential to achieve the targets being set.

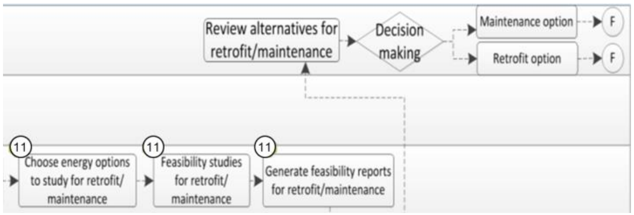

Figure 4 decisions making on whether to do maintenance or retrofit

The energy expert will use new methods to verify the process and the generated options while still having the power to alter the process of selection or add/reduce possibilities.

3.5 Decision making by the client and Produce of retrofit brief

At this point of the process a review of alternatives will be undertaken by the client using the decision support tool 11 to make an initial decision which is more suitable for the project, maintenance or retrofit. The feasibility results will be prepared in a format that will simplify the decision making of the client.

If decision is to retrofit, a model has to be created. It starts by the client producing the brief which contains the expected energy performance, the KPIs and setting up the targets. The next step is defining the specification of the ideal solution in relation to the given client requirements.

3.6 Creation of retrofit alternatives concept designs

The remaining stages of the model will be completed by an Architect who will conduct an environmental analysis and building performance assessment. The architect generates a project program. Using Tool 4 which is the BIM design tool he/she sketches the spatial outlines of the retrofit alternatives onto the existing BIM data on the basis of the defined indicators. The produced LOD4 models will be analysed by the architect taking into consideration the site implication and adaptability to the surrounding.

3.7 Improve retrofit model

The BIM model is then improved with material data for better energy efficiency performance and CO2 emissions reduction. In this phase the architect takes into account the embodied energy of the materials, use recyclable materials whenever possible, introduces new materials, figure 5.

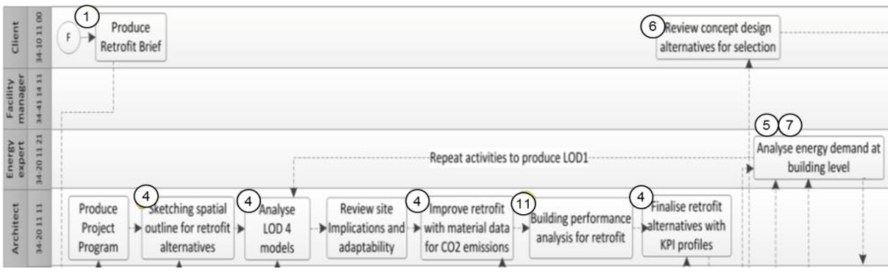

Figure 5 modelling of the retrofit alternatives and undertaking of performance assessments

3.8 Performance analysis for passive design

The architect has the option to choose to undertake some building performance analysis under the proposed retrofit alternatives using the energy efficient BIM. This procedure will mainly help to reduce the number of options that can be considered and even provide enough information to make the ranking on the basis of the chosen criteria from the list of the performance indicators. This procedure is conducted via the decision support tool 11 which is built on the top of an energy simulation tool, such as EnergyPlus, which is one of the most popular tools for dynamic building performance simulation. The decision support tool will perform building performance simulations to all possible retrofit scenarios preliminarily defined by the client and rank them using the chosen selection criteria.

3.9 Design concept and review by client

The architect finalises design alternatives with KPIs profiles using BIM and generate a design concepts for each potential alternative. Through the collaborative environment Tool 6 the client reviews the produced design concepts taking into consideration of his/her main requirements which include energy consumption, the construction cost and LCC.

3.10 Analysis of energy demand and Analyse energy alternatives at neighbourhood level

The energy expert will conduct an analysis of building energy demand using the energy simulation performance tool based on eeBIM Tool 5 and the energy match optimiser tool 7. Following this analysis the client via the collaborative environment will review of energy options for the selected retrofit options and narrows down the number of options which would be passed onto the architect on the collaborative environment Tool 6 to verify the BIM models of the selected alternatives in term of their energy matching potential. The energy expert will analyse the remaining retrofit alternatives from the previous steps for their higher potential to address the requirement already specified in the project and the pre-set targets using the target setting tool 1. The aim of this run of analysis is to evaluate the energy matching at neighbourhood level and rank them in their order of potential offered by each using a set of indicators which include energy price mode, renewable energy that is available or/and potential in the coming future and the existing or potential for energy production. At this stage the architect on the collaborative environment will review using the updated BIM models (with embedded energy matching results) with selected alternatives for their energy matching potential at neighbourhood level.

3.11 Final approval of selected alternatives by client

The improved BIM models for the selected retrofit alternatives will be accessed through the collaborative environmental tool 6 by the client for final approval. At this stage if there is more than one alternative they will be listed in a ranking order on the basis of the most important indicators to the client to enable fast approval. If the decision that all requirements are meet by one alternative, it is then final approved and the corresponding concept design is also approved.

3.12 Maintenance options and analysis of maintenance options

If the initial review alternatives (at defining the options for retrofit or maintenance stage) by the client using the decision support tool 11 has resulted that maintenance is the most adequate approach to follow then a number of maintenance alternatives will be generated. The FM will lead this activity and start by analysing the LOD4 BIM model. Originally the feasibility results (Retrofit/maintenance) are prepared in a format (ranked on the basis of most important criteria only and presented it on the collaborative environment at high level of information only) to simplify the decision making of the client. The FM will study all the maintenance options that can be considered. He/she will check the potential for site implications to identify the metrics for the relevant indicators. The ranges for these indicators will be used together with the indicators for energy matching at both building and neighbourhood levels, complying with existing regulations and the client requirements. The decision support tool 11 with its energy simulation feature will be used to analyse the building energy performance, shown in figure 6.

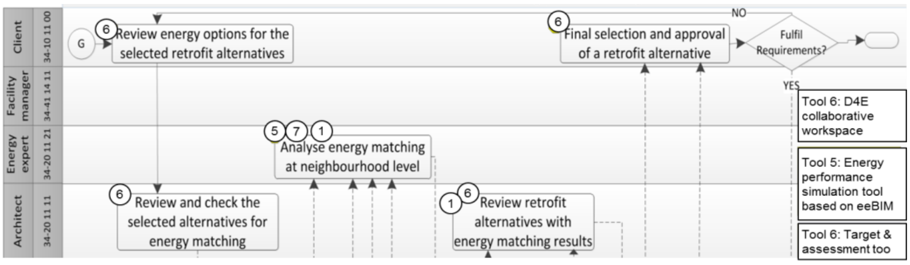

Figure 6 checking the retrofit solutions and evaluate the energy matching potential

3.13 Selected options, review by client and ready for execution

Key performance indicators will be used to narrow down the maintenance alternatives. Maintenance solutions will provisionally be ranked on their performance feasibility.

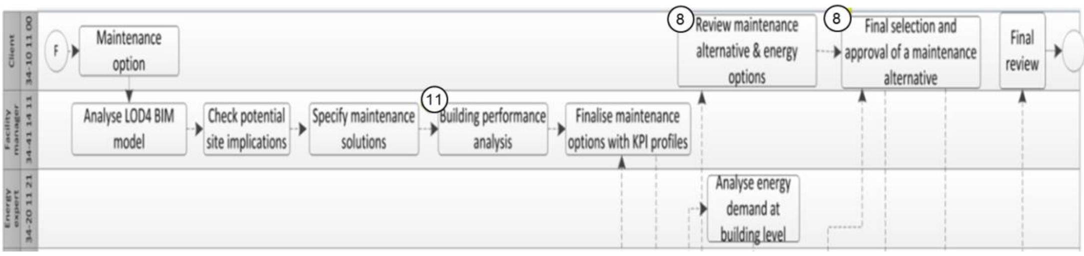

Figure 7 studying of maintenance options and making final selection

As shown in figure 7 the client will use the collaborative environment Tool 6 to review the maintenance alternatives and the energy options that are made available by the FM study. At a high level of information the client review will consider the analysis provided by the energy expert on solutions for their potential of reduced energy consumption, cost and LCC, energy matching at building and neighbourhood levels. This review process will result in a single maintenance alternative being approved by the client. Through the collaborative environment tool 6, various experts that are relevant to the different components included in the final solution will be invited to access the BIM model which embeds the maintenance solution. The HVAC engineer will use tool 8 (BIM HVAC design and simulation tool) to analyse the final solution for its feasibility, compliance and adequacy to fulfil all relevant stake holders' requirements. Similarly the electrical engineer will use Tool 9 (BIM electrical design and simulation tool) to verify that the solution selected is adequate to respond to the identified requirements.

4. Specification of the functional requirements for DS tool,

The decision making in retrofit and maintenance projects is supported by the energy simulation and actions for environmental influence through provision of energy system performance data and physical characteristics of building materials; cost simulation over the life cycle through e.g. the provision of data from similar real cases; design process through possibilities to share design results; owners' decision through providing information on the utilization and sustainability aspects of existing components and energy systems; and FM decision in choosing the optimal action for the available boundary conditions. The functional requirements for retrofit and maintenance design scenario are discussed and an exhaustive list is generated. Most of these requirements will be focusing on components identification, compliance with regulations and how to undertake the adequate modelling and simulation for retrofit and integration. Table 1 shows the identified different requirements for the different users.

Table 2 requirement for the different users

User	**Function required**
Owner/Facility manager	Digital trading function
Architect	Decision support / optimisation function
	Energy simulation function
	Energy matching & consumption estimation function
Building Energy designer	Information acquisition function
Information exchange	Filtering data & interlinking function
	Interaction with 3D sketch service
Building energy designer	Neighbourhood information acquisition and analysis function
	Visualization functional module

5. Databases requirement

These will be captured from: Original brief from clients; Assessed against: building regulations; building design standards from ASHRAE, ISO and CIBSE, or commercial building performance rating methods such as BREEAM and LEED. Furthermore, through engaging existing users in workshops or through organised surveys. Some relevant examples could be requirement for more double glazing to meet the new standards; measurement of air tightness; measurement of natural daylight; need for smartness to support day to day activities; review of design life of different components; analysis of sensors data. The methodology adopted to identify the DB requirements for FM decision support included: Questionnaires and interviews with relevant end users. 30 responses were collected from different sectors, see Figure 2 and 3. 23% are Architects and designers, and another 20% are technology and solution providers.

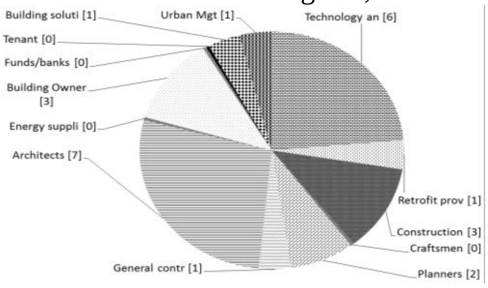

Figure 2 Stakeholders participation

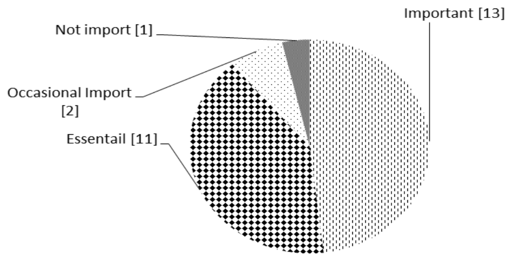

Figure 3 Opinion on building component

Building components initially have to be manually stored by users. The DB requirements as reported from the literature search included: (i) User, through interaction has to provide a direct link to BIM models; (ii) Visualising data, choices of building architecture; (iii) BIM models, have to be accessible by relevant stakeholders such as engineers for energy systems; (iv) Solutions with their operational attributes, maturity, deterioration, experienced costs or best practices of similar projects; (v) Material characterization (e.g. type, functionality, thickness, thermal conductivity, density specific heat, internal and external solar absorption, and emissivity); (vi) Team management.

5.1 Operation and maintenance data requirements

Table 4 Indicators for retrofit and maintenance

	Indicator		Indicator
1	Occupant involvement	15	CO2 reduction targets
2	Client awareness	16	ROI
3	Building performance assessment	17	Potential for energy generation

The methodology adopted to identify the database requirement in terms of design for operation and maintenance besides of review of relevant literature, included standards and guidelines to first highlight the generic domains of requirement. The survey was conducted with the aim of gauging more specific requirement to different usage groups on databases which will support design for building operation and maintenance. During a workshop with experts in retrofit and maintenance the database requirements are extracted and discussed leading to the specification of the necessary structure and content with a certain level of details. Table 4 shows the list of indicators for retrofit and maintenance are used to characterise the requirements.

6. System architecture of the decision support system

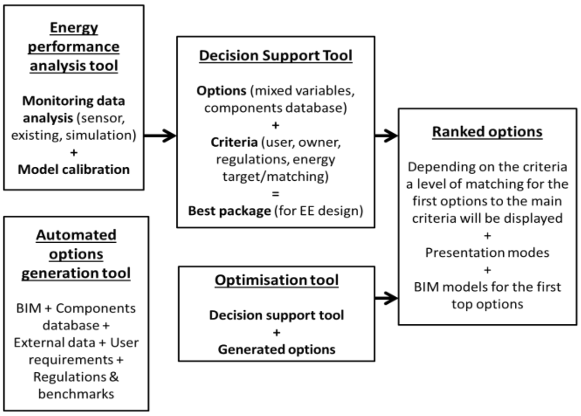

Figure System architecture of the decision support system

The decision support tool was structured using four building blocks which are: (i) energy performance and simulation block; (ii) retrofit and maintenance options generator; (iii) optimisation block and; (iv) the decision making block that is based on Multiple Criteria Decision Making (MCDM) method. Decision support tools have already been developed for architects and building designers to choose the best building design options with retrofit and maintenance in mind.

The proposed DS tool would support Facility Management (FM) to design their option on building Information Model (BIM) file through making best decisions during retrofit and maintenance for improved energy efficiency (EE) without having full knowledge of the latest technologies in any required subject and without being an expert in building energy performance analysis and simulation.

Within Design4Energy which is the sponsoring EU project of this work three architects and other end users of the retrofit and maintenance decision support tool are partners and are active members who were involved in shaping and testing the work being described in this paper. An initial exploration has also been undertaken with a larger number of external architects and facility managers to agree and feedback on the format and the content of the decision support tool and its corresponding components. At later stage of this development it is intended to embed it into a holistic design platform during which a program of validation and demonstration will be conducted with a much larger pool of end users.

7. Conclusions

An identification of the required data structures and databases to support designers and enable Facility Management (FM) to make decisions on best retrofit and maintenance for improved EE has been conducted. The databases requirements and functionalities have been detailed. A set of necessary databases were proposed to enable optimal decision making by FM and perform adequate design of new build. The level of detailing the database requirements is provided in terms of information technology (IT), components and systems, materials and the stakeholders. To complete the study a validation by FM of the database is conducted using the new decision support tool for maintenance and retrofit to be used. The work focused on using building simulation to predict the effectiveness of various retrofit measures and inform the current development of a dedicated decision support tool for FM in particular definition of database requirements in terms of components, parameters and indicators to automatically generate all possible retrofit or maintenance options. Analysing existing database solutions was the first pre-requisite, then identification of databases' characteristics using focus groups of potential users (architects, energy designers and FM) and finally tuned to suite the type of decision support tool being developed. Decision support tools have been key in the providing smartness of many design platforms. System architecture was therefore developed for embedding the set of decision making tools into the platform. A retrofit and maintenance scenario was used to follow through the decision making process for which the necessary tools were specified in terms of their functionality and then designed.

8. Acknowledgements

Design4Energy project is co-funded by the EU Commission, Information Society and Media Directorate-General, under the Seventh Framework Programme (FP7), Grant agreement no: 609380. The authors wish to acknowledge the Commission for their support and the project partners for their contributions.

A Settlement of the Internal Heat Gain Schedule of LES (Living Environment Simulator) Using Statistical Data

Hyun-Jung Choi, Sun-Ho Cho, Yu-Min Kim and Gyeong-Seok Choi

Building and Urban Research Institute, Korea Institute of Civil Engineering and Building Technology
Email: mingineu@kict.re.kr

Abstract

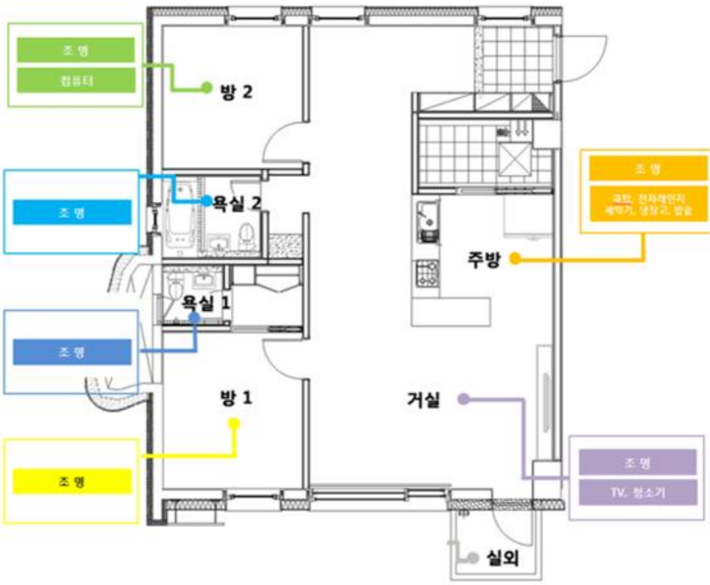
The purpose of this study is to set internal heat gain schedule of LES (Living Environment Simulator) using statistical data and suggest total daily electricity consumption and time of maximum power generation based on set schedule. The result indicates that time of maximum power generation is individual and household labor activities and total daily electricity consumption is 6.5 kWh/day in weekday and 7.5 kWh/day in weekend. An additional study is required to review total yearly electricity consumption through setting internal heat gain schedule in winter and summer season on the basis of this work.

Keywords: Occupancy Schedule, Lighting Schedule, Equipment Schedule, Electricity Consumption

1. Introduction

As of 2008, approximately 12% of total energy consumption in buildings in the country is consumed in homes, and electricity consumption accounts for the highest ratio among the energy consumption in homes. The electricity consumption in homes is expected to increase gradually due to the improvement in the standard of living and enlargement of home appliances, and in order to reduce electricity consumption, it is necessary to estimate electricity consumption in the building and identify the form of energy consumption in the building by analyzing the pattern of home appliances usage which is directly and indirectly related to electricity consumption and the behavior pattern of occupants. However, there is no objective and reliable methods regarding setting of home appliance usage pattern and the behavior pattern of occupants presented in the country currently, and preliminary data required for estimating electricity consumption in the buildings is also insufficient.

Based on this background, the purpose of this study is to set the occupancy, lighting and equipment schedules of LES (Living Environment Simulator) implemented in Zero-carbon Green Home of Korea Institute of Civil Engineering and Building Technology (KICT) by using Statistics Korea's report on the time use survey1) and Korea Power Exchange's report on investigation of



home appliance distribution rate and electricity consumption pattern at home2) and present electricity consumption on LES home for one day and the time of maximum electricity consumption.

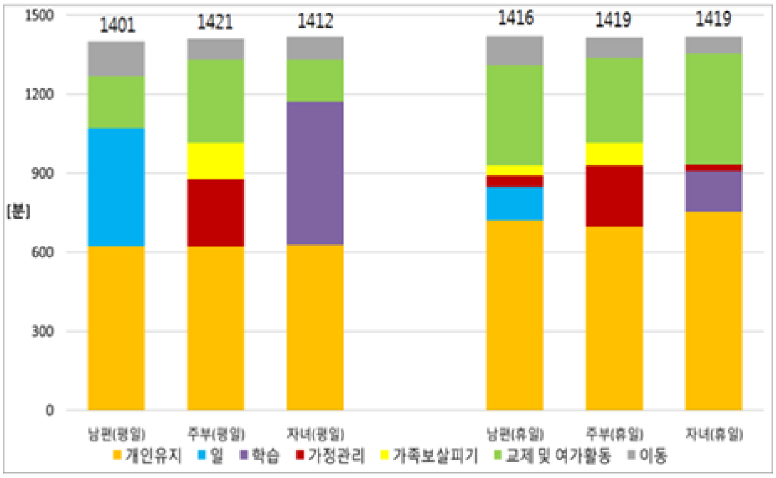
2. Setting of Internal Heat Gain Schedule

2.1 Summary of LES(Living Environment Simulator)

LES was implemented for the purpose of optimizing the operation of Zero-carbon Green Home by monitoring the quantitative electricity consumption while controlling the uncertainty of living environment.

The area of LES implemented house is 58 ㎡ consisting of the living room, kitchen, room 1, room 2, bathroom 1 and bathroom 2, and home appliances including lighting, TV, computer, refrigerator, washer, rice cooker, microwave oven, cook-top and vacuum cleaner are installed in the house. 3 household members were set for LES by referring to the 2010 Population and Housing Census Report3) and single-income family with a junior high school student was assumed by referring the gender and age distribution of householder. For the household members, 6 sets of bodies that humidification and heating control were available were established and placed on the living room (3 Sets), room 1 (2 Sets) and room 2 (1 Set).

Figure 1: Floor plan of LES



2.2 Selection of representative behavior of household members and linkage of home appliances

Since electricity consumption is affected by the behavior of occupants, it is necessary to set the schedule by determining major behaviors of occupants that consume electricity. In this study, the major behaviors of occupants were selected by referring to Statistics Korea's report on the time use survey in 2009. In the report on the time use survey, the result of sample survey and estimation of people aged 10 or older how they utilized 24 hours a day for 5 years is presented separately by class.

In this study, the representative behavior time of household members was selected separately into weekdays and weekends based on the average time of householder, his spouse and a child in middle school of single-income family, and any behavior corresponding to less than one percent of 1,440 minutes a day (approximately 15 minutes) was excluded.

Table 1 above shows the relevant actual lighting and home appliances related to the representative behavior selected earlier. For the home appliances, only home appliances placed in LES home were applied, and the refrigerator and rice cooker not presented in Table 1 were set to operate 24 hours.

Figure 2: Mean Time of Representative Behavior

Table 1: Relationship Between Behavior and Home Appliance

Behavior		Lighting	Appliance
Individual activities	*Sleep*	-	-
	Meal	*Kitchen*	*TV*
	Refreshments	*Kitchen*	*TV*

2.3 Setting of Internal Heat Gain Schedule

Before setting the indoor heating gain schedule, the procedure to set 1,440 minutes for the sum of average representative behavior time of household members and the procedure to adjust the home appliance use time at 5-minute interval were carried out.

As shown in Figure 2, the sum of average behavior time of each household member for each weekday was less than 1,440 minutes because the behavior not to use home appliance was excluded in the procedure to link the representative behavior of household members and home appliances so that the time for the relevant behavior was omitted. In order to set 1,440 minutes for the total sum, the procedure to add the omitted time to the relevant behavior by considering the ratio of average time of each behavior to total time was carried out, and it is presented in Table 2.

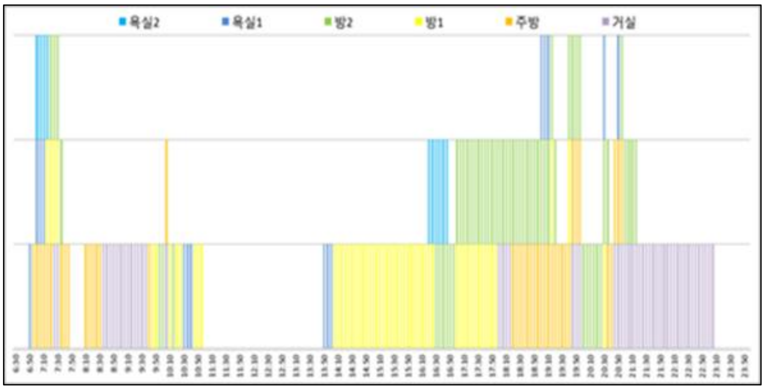
Table 2: Rearranged Mean Time of Behavior

Behavior	*Weekday[minute]*			*Holiday[minute]*		
	Householder	*Spouse*	*Child*	*Householder*	*Spouse*	*Child*
Individual activities	*630*	*630*	*630*	*720*	*700*	*760*
Household labor	*0*	*270*	*0*	*50*	*250*	*30*
Human relations & Leisure activities	*210*	*330*	*180*	*390*	*320*	*410*
Learning	*0*	*0*	*540*	*0*	*0*	*180*
Family care	*0*	*130*	*0*	*40*	*90*	*0*
Labor	*480*	*0*	*0*	*120*	*0*	*0*
Travel	*120*	*80*	*90*	*120*	*80*	*60*
Sum	*1440*	*1440*	*1440*	*1440*	*1440*	*1440*

The time of home appliance usage was adjusted at a 5-minute interval by referring to statistical data of Korea Power Exchange's report on investigation of home appliance distribution rate and electricity consumption pattern at homes, and 50 minutes a day were set for the time of cooktop usage which was not presented in the report by considering the average home management time.

Table 3: Time Use of Home Appliances

Item	*Report[minute]*	*Rearrangement[minute]*
TV	*350*	*350*
Washing machine	*92*	*90*
Computer	*211*	*210*
Electric rice cooker	*535*	*1440*
Microwave	*20*	*20*
Vacuum	*35*	*35*
Refrigerator	*-*	*1440*
Cooktop	*-*	*50*



The internal heat gain schedule on weekdays during intermediate season (March ~ May, September ~ November) was set based on the average behavior time of household members and the time of home appliance usage and presented in Figures 2 ~ 4, and the weekend schedule was omitted for lack of space. The schedule of relevant behaviors was set first for the occupancy schedule of household members by referring to bedtime, wake-up time, time to start to eat, eating time, time of movement presented by Statistics Korea and other behaviors were set by referring to the time of home appliance usage and the number of bodies installed on each room. Lighting was set to operate while a household member occupied regardless of the intensity of solar radiation brought into indoor, and hourly usage rate on weekdays and weekends presented in Korea Power Exchange's report on investigation of home appliance distribution rate and electricity consumption pattern at homes was referred for the time of home appliance usage, and setting method was classified based on the time of home appliance usage. In case of a home appliance which was used for a long period of time, it was set to use at the time that exceeded the average daily usage rate, but in case of vacuum cleaner, washer and microwave oven that were used for a short period of time, it was set to use at the time of highest usage throughout the day.

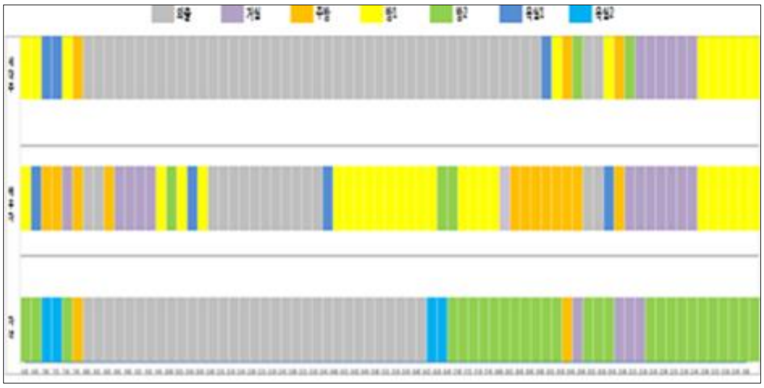


Figure 3: Occupancy Schedule

Figure 4: Lighting Schedule

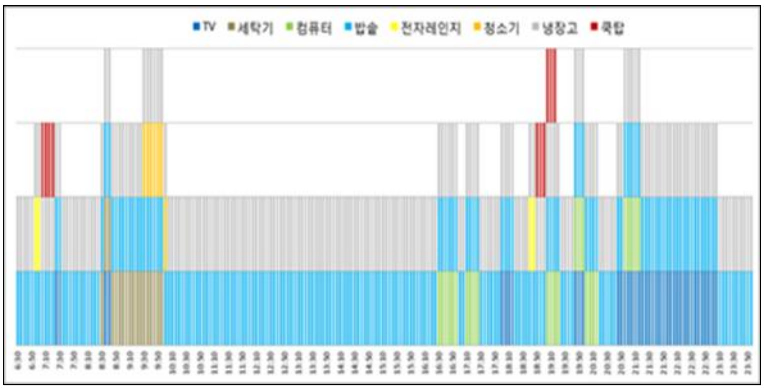

Figure 5: Equipment Schedule

3. Calculation of amount of electricity used

Based on lighting and equipment schedule, the calculation result of amount of electricity used for each hour on a weekday during intermediate season (March~May, September~November) was shown in Figure 5. The calculation result showed that the largest amount of electricity used on weekdays and weekends occurred between 7:30 AM and 8:30 AM and between 7:30 PM and 8:00 PM on weekdays and between 9:30 AM and 10:00 AM and between 6:15 PM and 6:40 PM on weekends which were the home management and personal maintenance activity times. The daily total electricity consumption was approximately 6.5 kWh/day on weekdays and approximately 7.5 kWh/day on weekends which were lower than 10 kWh/day presented in the precedent study4) used for comparison and verification with actual electricity usage. However, the electricity usage was calculated by designating only home appliances placed in LES as the items for calculation, so in order to draw the result which is close to actual electricity consumption in future, a study will be carried out by adding home appliance items.

4. Conclusions

In this study, the occupancy, lighting and equipment schedules of LES were set by utilizing the statistical data of Statistics Korea and Korea Power Exchange, and the time of maximum power generation and total daily electricity consumption at LES home on weekdays and weekends were presented based on the set schedules.

The annual amount of electricity used will be reviewed in future through winter and summer schedule setting by considering the heating and cooling apparatus.

Life Cycle Cost-Efficient Near Zero Energy Hall Building for Nordic Climate

Jyrki Kesti

Ruukki Construction Oy, Finland
Email: jyrki.kesti@ruukki.com

Abstract

Finland’s first nearly zero-energy single-storey commercial/industrial building was completed in the spring of 2015 in Hämeenlinna. Built on the campus of Häme University of Applied Sciences (HAMK), the building is used for R&D and teaching purposes by the university and Ruukki Construction. There are only few years before the EU near-zero energy requirements will come into effect and thus it’s important to get real experiences of solutions before design of these buildings will be started. As a main result, the construction project was able to show that a building meeting these requirements and exceeding today’s strict energy-efficiency requirements by over 60 per cent can be built at a profit. In order to achieve the targets, special attention was paid to the steering of energy and life cycle efficiency during the whole project from early phase planning to the execution. Smart design and combination of different techniques including renewable energy sources enabled the end result that meet clearly forthcoming nearly zero energy regulations. Several techniques were utilized in the building. First, the energy need was minimized for example by extreme air-tight envelope and effective heat-recovery in the ventilation as well as by day-lighting utilization. Renewable energy sources have been utilized with an innovative way with building integrated solutions. In the ground energy system, the foundation piles have been utilized for heating and cooling energy extraction. Solar heat collectors have been used for boosting the energy pile system by charging the soil with solar energy. The life cycle optimization was based on integration of building energy simulations and cost calculations. This enabled to find the most cost optimum total solution to meet the future high energy targets.

Keywords: near zero energy building, energy pile, day lighting, life cycle costs, cost optimum

1 Introduction

Energy efficiency has risen to the same level as construction quality and cost efficiency to become one of the most important factors guiding construction projects. Investments in energy efficiency have already been made, particularly in residential and office construction. Single-storey commercial and industrial facilities are one of the most important building segments for steel construction in the EU. This building segment also has a relatively short life span, thus the building stock renews quickly compared to many other segments. These factors combined will validate the importance of energy-efficient solutions in new construction in this particular segment. In energy efficient concepts, buildings must be designed and executed as complete entities – not split up into subareas that are sub-optimized separately. This approach is almost contrary to present-day construction, in which design and build are split up across several parties without the overall entity being properly managed. The execution of commercial, industrial and logistics buildings could be managed by, for instance, so-called alliance agreements, in which the parties involved are bound to share responsibility for executing buildings in accordance with customer requirements (in addition to technical cooperation).

More complex construction requirements, such as cost efficiency, quality, energy efficiency and environmental friendliness, also underline the need to plan and manage entities as a whole. Finland's first nearly zero-energy "big-box" type single-storey building (nZEB) for commercial, logistic or industrial use was designed and constructed to meet an objective: to be a building with an economical lifecycle that saves energy and uses existing renewable energy sources (See Figure 1). In this project, special attention was paid on the co-operation with different parties and commitment to the common targets.

The new structure was designed and executed to enable economic use of the building and optimization of construction solutions. Optimization means selecting solutions based on investment outlays, additional usage costs and future savings. A well-insulated and airtight envelope in the building's walls and roof enables savings in energy requirements, and the use of solar power, day-lighting and geothermal energy harness renewable energy for use in the building. The building's economic performance was estimated by comparing the investment costs and life-cycle costs of a reference building and an nZEB building. The reference building level was agreed with the customer and designers.

Figure 1: Completed nearly zero-energy building in Hämeenlinna, Finland

2 Technical solutions for the nearly zero-energy building

2.1 Building envelope

The shell of the building walls and roof are highly significant for its energy efficiency. For this reason, the outer walls of the building are fitted with sandwich panel system, with ultra-airtight panels and carefully designed and executed seals between the panels, plinth, roof, windows and doors. The sandwich panels are composed of a glass-wool insulating layer between two thin steel sheets. The thickness of the insulation in both the wall and the corner panels is 230 mm, with a U-value of 0.16 W/m^{2}K. The building's roof incorporates a new type of prefabricated PIR roof elements with a U-value of 0.12 W/m^2K. Airtightness of the entire building has very big role in the heating energy demand. The measured airtightness of the entire building was as low as q_{50} = 0.76 $m^3/h,m^2$. Based on energy simulation, the heating energy need of this building with this level is 28% lower than that of the building with minimum air-tightness of q_{50} = 4.0 $m^3/h,m^2$, based on Finnish energy regulations.

Figure 2: Energy panels with decorative printing.

2.2 Utilization of day-lighting

The sizes and directionality of the building's windows are optimized for energy efficiency. The large windows are aimed south-west. The need for artificial lighting is reduced by the windows, due to their directionality and surface area. Traditional large windows bring light in – but also conduct heat out. In this building, the glass windows facing south have been replaced by cell windows made of polycarbonate (See Figure 1). These "daylight" windows isolate heat well – the warm rays of the sun during the summer do not heat the premises. During periods of bright daylight, light coming through traditional windows in indoor areas causes glare. Instead of this, daylight windows distribute light into the premises in a pleasantly even manner without glare, and blinds are not needed. The building is equipped with a day-lighting control to reduce artificial lighting. The U-value of these day-lighting windows is approximately 0.84 W/m^2K. The north-east wall of the building incorporates Ruukki Construction energy panel system clear windows, forming a dense structure with the panels. Lighting simulations, carried out by Tallinn Technical University, showed that the lighting energy saving potential is over 50 % in those spaces where day-lighting windows were used (high part of the building). Comparison of the lighting energy use with different lighting levels is shown in Figure 3.

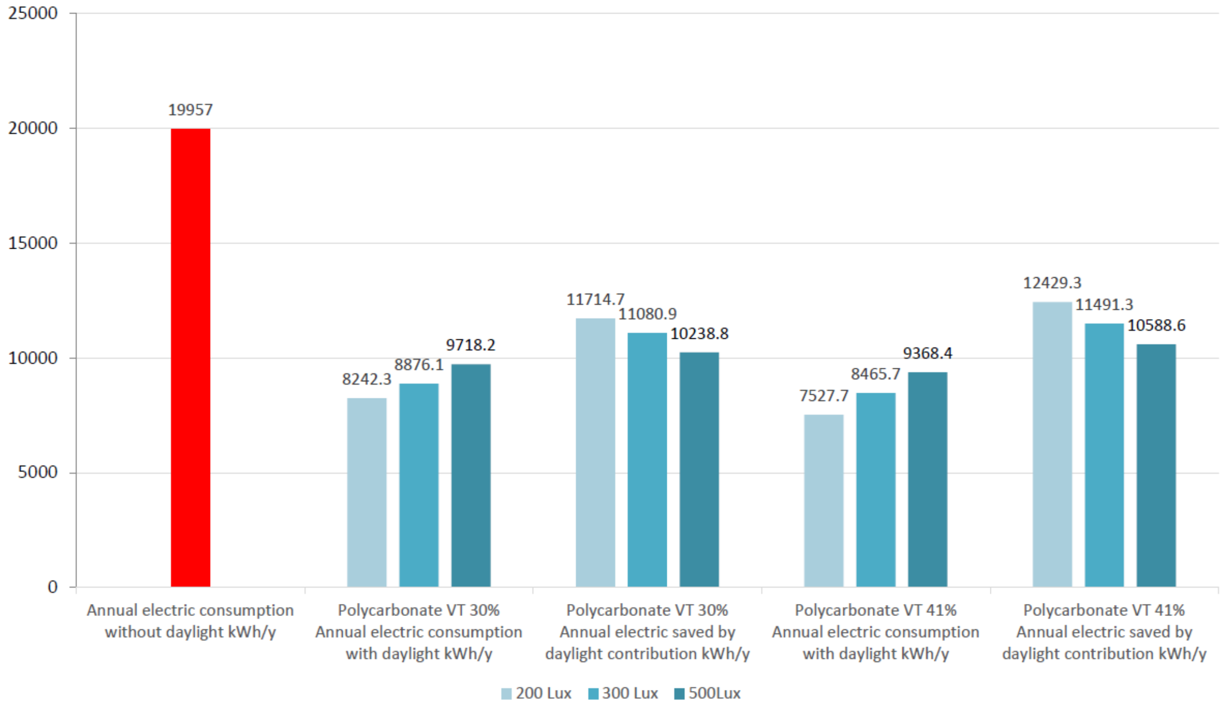

Figure 3: Energy saving potential of the day-lighting control (Building use: weekdays 8-17) for different lighting levels and different light transmissions (VT) of polycarbonate sheets.

2.3 Heating, cooling and ventilation systems

New types of radiation-based heating and cooling profiles developed during the project are installed in the building. The profiles are affixed to the underside of the roof element as shown in Figure 4. The radiation profiles generate either cools or heats the interior, depending on the season and the desired indoor temperature of the building. Radiant profiles work with a low temperature difference to the ambient air, allowing the heat pump installed in the building to perform well. The radiant system also reduces temperature variations on each floor in the building, thereby considerably increasing usage comfort and improving well-being at work and productivity.

Figure 4: Ruukki radiant profile and installation

Heating and cooling performance of the new product was studied with Comsol Multiphysics program by Finnish company Granlund Oy. Product properties such as material, colour, tube diameters and geometry were optimised with the tool to achieve high performance system. Share of the radiant part of the total heat output is about 76% and the total heating power is 77 W/m with average fluid temperature of 45ºC. In cooling mode, the cooling power is 31 W/m with average fluid temperature of 16,5 ºC. Temperatute distribution of the studied system in heating mode is shown in Figure 5.

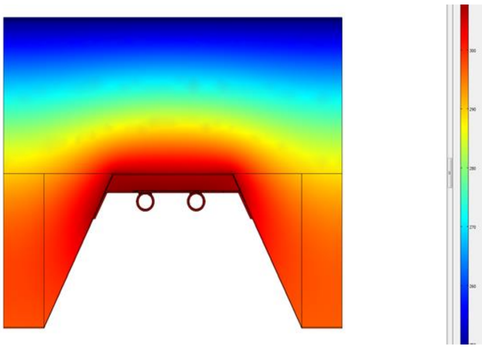

Figure 5: Ruukki radiant profile integrated into the roof panel.

A new type of indoor heating and cooling system also reduces energy consumption compared to air-heating systems. A ventilation airflow is now required only for the influx and removal of fresh air – not actually for heating the premises. The mechanical ventilation machine is equipped with an 80% heat recovery system.

2.4 Renewable heating energy system

Geothermal energy is utilized for the building's heating and cooling requirements. In total, 60 Ruukki Construction energy piles with diameter of 115mm and of 11m in length under the floor and columns are incorporated in the foundation to use renewable energy to heat the building. The energy pile system is based on steel foundation piles, Uponor double U-heat-collecting pipes (ϕ25mm) installed in the piles, connecting pipes via manifolds to the heat pump, and heat-transfer liquid. Figure 6 shows the heat collector pipes installed. Furthermore, two conventional heat wells of 200 m in length were installed for heating and free cooling of the building. The heat pump capacity is 32 kW. The performance of the steel energy pile system in Nordic conditions has been studied in several studies, for example by Nyholm (2011), Cervera (2013), Hassani (2014) and Döring et al (2015). According to these studies it have been showed that recharging of the energy pile field during the summertime is essential in order to guarantee the long-term behaviour of the system.

Figure 6: Heat collector pipes installed in the floor slab piles

A total of $24m^2$ of Ruukki Classic solar collectors are installed on the roof of the building's technical area. The Classic solar system integrates fully with the roof, as shown in Figure 7. Solar collectors accumulate thermal energy from the sun and transfer it to the soil through the energy piles. The soil is charged whenever there is heating potential available – even in January, thanks to the very low temperature level in the ground.

Figure 7: Roof-integrated solar heat collectors

The soil acts as a seasonal thermal reserve, much like a battery. Beneath the building, a clay layer extends to a depth of 11 metres. Clay has a greater thermal storage capacity than, for example, gravel. During the summer, the energy pile loop is closed from the heat pump, and is charged by the solar collectors. In the winter, the piles transfer energy from the soil to heat the building with help of heat pump. Cooling of the building is via the deep heat wells by free cooling utilizing the low temperature of the ground rock. The principle of the system is shown in Figure 8.

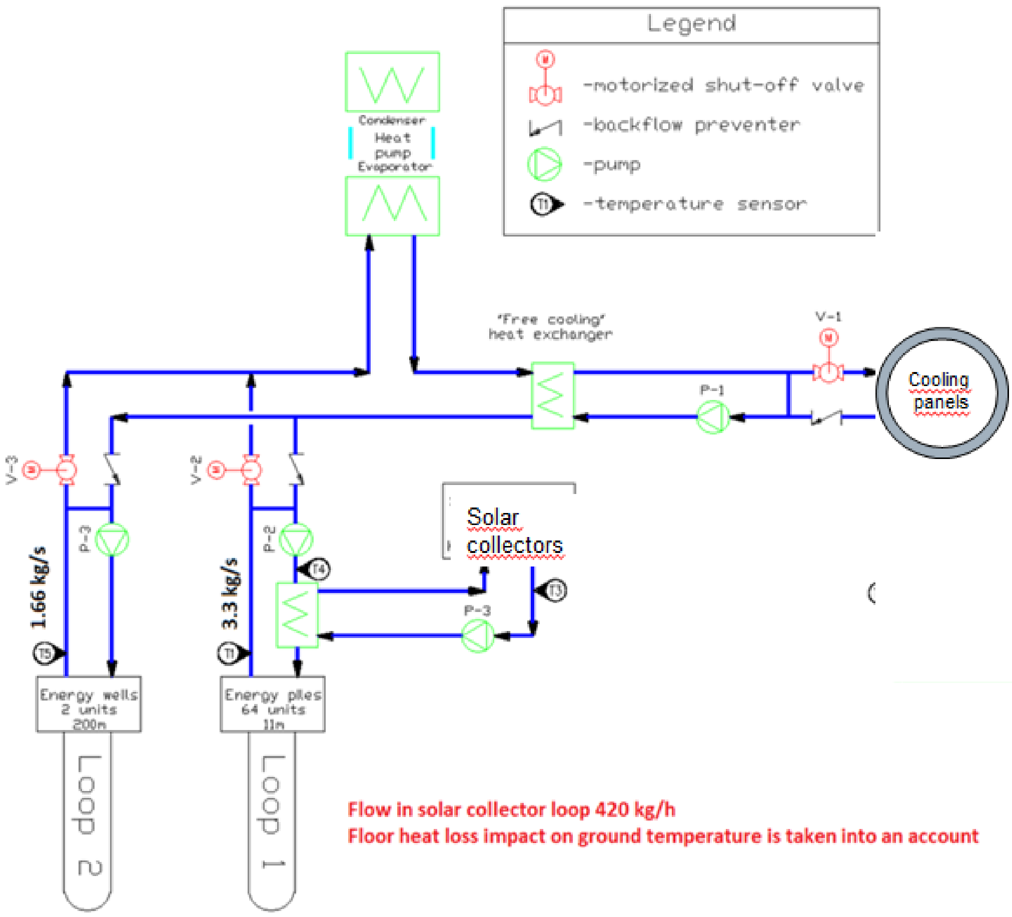

Figure 8: Ground energy system

2.5 Building Integrated Solar Energy Solution

Solar power is also used in the outer walls of the building. Ruukki Construction's on-wall solar panels, which generate electricity from the light of the sun for the building's network, are installed on its southern façade. A total of 61 m^2 PV (Photovoltaic) panels with total peak power of 10 kW are incorporated in the wall (see Figure 9). The optimum amount of solar PV-panels is based on buildings own electricity, because it's not economical to feed extra electricity into the public electrical network. Total electricity production of the system is about 7 MWh/year. In Finnish latitude the on-wall system is relatively effective, because of low angle of the sun.

Figure. 9: Building-integrated solar PV panels installed on the southern facade

2.6 Monitoring of the building

The building is equipped with a large number of energy meters and other measuring devices to ensure extensive monitoring and ascertain the real energy performance of the building. In particular, the energy pile and solar heat systems are monitored carefully to study the soil behaviour in the long run. Some building elements are also equipped with thermal-moisture sensors in order to monitor their condition throughout their life-cycle. Furthermore, the amount of snow on the roof is also monitored with a Ruukki Smart Roof application based on strain gauge measuring of the metal roof structure.

3 Building simulations

The energy efficiency of the reference building and the nZEB were determined by energy simulations with the IDA ICE 4.5 program (Equa Simulations 2014). The simulations were performed by Ruukki and Tallinn Technical University. The reference building represents the current normal, already very energy-efficient, construction custom. A simulation model included a model of the building with the structures and technical systems as well as the energy piles and heat wells. The initial data for the reference case and the nearly zero-energy case are given in Table 1. Many different alternatives were studied in order to find optimum solutions to the whole building. Special attention was paid to design and model the energy pile system carefully to guarantee long-term performance of the system. One important observation of the simulation was that further to recharging the soil with solar energy, heat losses though floor structures also help to keep energy pile field well balanced.

The final results for the energy demand and the delivered energy are shown in Tables 2 and 3. A comparison of delivered energies of the cases is given in Figure 10. The results show that it is possible to over than halve the total energy use of a building with smart design and solutions.

Table 1: Initial data for simulated cases

	Reference	nZEB
Wall, U-value	0.17 W/m2K	0.16 W/m2K
Roof, U-value	0.09 W/m2K	0.12 W/m2K
Window, U-value (avg)	1.0 W/m2K	0.87 W/m2K

Pumps electricity	6254	4.2	6254	4.2
Lighting	19498	13.0	19498	13.0
	Total electricity:		**61578**	**41,2**

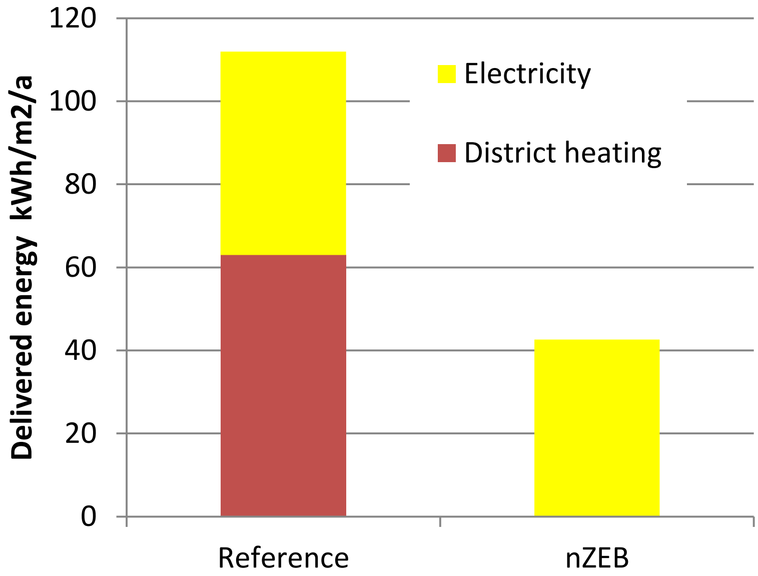

Figure 10: Comparison of deliverd energies of the reference case and nZEB case

Furthermore, the annual yield of the building-integrated solar PV panels is approximately 7000 kWh/a. Thus the need for delivered energy decreases further by approximately 5 kWh/m^2, corresponding to a decrease in a primary energy use over 10%.

As yet there are no official requirements for nearly zero-energy levels in Finland, but the proposals made in the national “FInZEB” project (FInZEB 2015) indicate that this building would clearly meet future targets.

4 Economic feasibility studies

Economic feasibility studies and comparisons between the two cases were carried out. The economic calculations took into consideration all investment costs that differed in the two cases as well as future energy savings due to improved energy efficiency. The net present values of the future savings were determined based on a 6% interest rate and a 4% increase in the energy price. The initial price of electricity was 85 €/MWh and 65 €/MWh for district heating. All prices are excluding VAT. The results are shown in Figure 11. As Figure 11 shows, the nearly zero-energy solution is economically reasonable, with a payback period of around 9 years. Also, it should be noted that the real extra investments of the nZEB solution are only about 2% of the total construction costs. Solar PV installations are not included in the studies, because they were not included into the original design and their impact is easy to separate from the overall building energy performance. The separately calculated payback for solar PV installations is approximately 15 to 20 years.

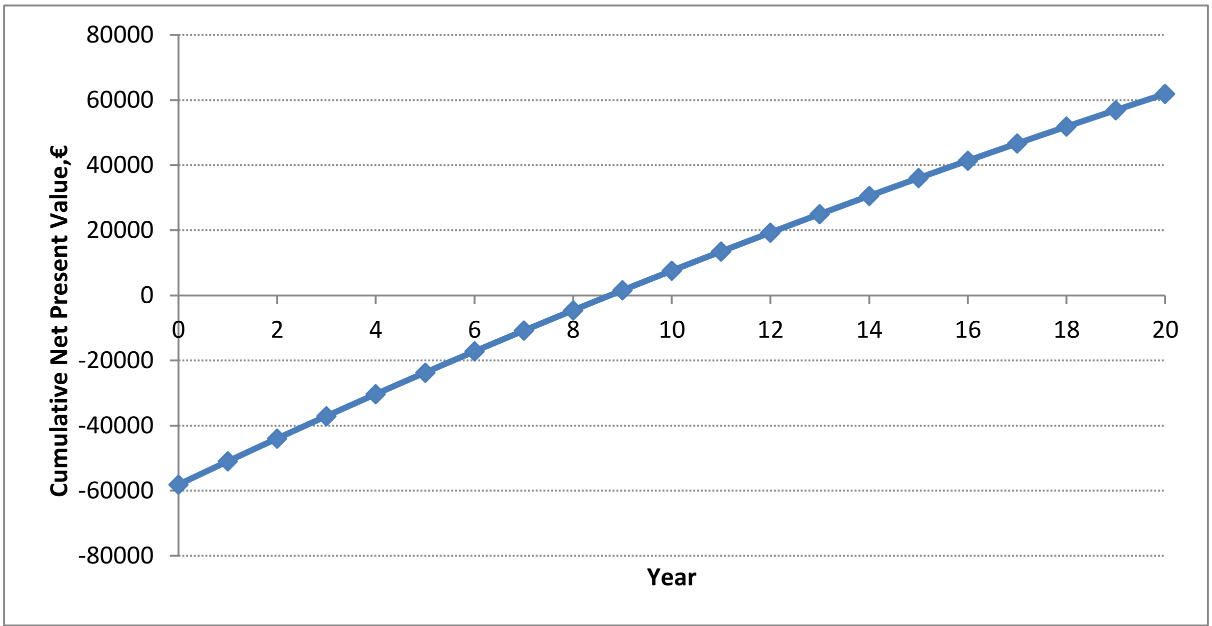

Figure 11: Net present values for the nearly zero-energy building compared to the reference building

5 Conclusions

The project showed that the nearly zero-energy building is technically feasible if the energy demand of the building is reduced and renewable energy sources are utilized in a smart way. Energy simulation tools came in handy in the early design phase of the project. Air-tightness of the building proved to be one of the most important factor in the reduction of energy demand. Lighting simulations showed that there is also lot of potential in utilization of daylighting in this kind of buildings. Solar collector boosted energy pile system proved to work well to produce heating energy to the near-zero energy building. The project also showed that the nearly zero-energy buildings can be constructed in a Nordic climate in a cost-efficient way. The extra costs of energy efficiency may be very low if the building is optimized as a whole – not via sub-optimizing.

Notation

AHU	Air Handling Unit
EPS	Expanded Polystyrene
SCOP	Seasonal Coefficient of Performance
DHW	Domestic Hot Water
nZEB	Near Zero Energy Building
SEER	Seasonal Energy Efficiency Ratio
HR	Heat Recovery of the ventilation system
q_{50}	Air-tightness of the entire building [$m^3/(h \cdot m^2)$]
PIR	Polyisocyanurate insulation
SFP	Seasonal Factor of Performance
U-value	Heat conductivity [$W/(m^2 \cdot K)$]
VT	Visual Light Transmission

Abstract

In recent years, many new, enlarging and rebuilding civil transportation airports are under construction along with economic development. But the problems of environmental damage of civil transportation airports which have caught more and more attention in public are becoming the barrier to the civil aviation development. Based on the theory of environmental sociology, sustainable development and green airport, this paper have summarized the environmental management measures of international civil transportation airports and the laws related airport environmental of different countries. Then the life-cycle environmental management system framework of civil transportation airport is put forward, which points out that environmental management require integrated management through three dimensions, namely environmental management contents dimension, life cycle dimension and environmental management technology dimension. At last, in order to offer a new possible method for airport environmental management in operating period, the early warning system of civil transportation airport based on gray system theory is established and proved feasible through a simple case. The results of this paper can be the theoretical basis for the life cycle environmental management of civil transportation airport and contribute to solve the existing problems of environmental management of civil transportation airport.

Keywords: civil transportation airport, environmental management, life-cycle, environment early warming, grey system theory

1. Introduction

The amount of civil transportation airports is continuously increasing as the development of economy and the improvement of people's demand. However, the development of civil aviation industry has brought serious environmental pollution (Chen, Z., Li, H., & Hong, J., 2004) which causing that people living near the airport put up protests against airport pollution more frequently in recent years. For example, the Heathrow Airport (UK) expansion project has been protested because of environment pollution (BBC news, 2015) and Frankfurt airport has been protested by nearby residents for more than 10 years because of night flight noise pollution (Ta Kung Pao Hong Kong, 2012). Civil transportation airports projects have a great impact on the environment in construction period and operating period, so the environmental pollution problems will be a main barrier to the development of civil transportation airports in both the present and the future.

FAA (Federal Aviation Administration, 2012) pointed out that the environmental problems of airport are the most important in the design and operation of a new airport. At present, the developed countries usually publish various laws and regulations related airport environmental to regulate the construction and management of airport. International airports have their own methods of environmental management, including recycling, low-carbon and intelligent measures. We have sort out some environmental management measures of airports, as show in Table 1.

Table 1 Environmental Management Measures of Airports

Airport Name	Environmental Management Measures
Manchester Airport (UK)	Integrate environmental management into the business operation.
Oakland International Airport (American)	Implement the strategy of sustainable development including includes three parts: environmental responsibility, economic vitality, social equity; draw up rules of plane landing and taking off at night; build the noise isolation area near the airport.
Heathrow airport (UK), Hamburg airport (Germany), Frankfurt airport (Germany), De Gaulle airport (France) and Narita airport (Japan)	Charge relevant fees according to the noise DB level.
Phoenix Sky Harbor International Airport (American)	Through well design in the construction, every energy consuming equipment of the airport is intelligent which is able to be automatic power off when is not required
Athens International Airport (Greek)	Provide 422000 m^3 reuse water for agricultural irrigation
Guangzhou-Baiyun International Airport (China)	Put the idea 'land conservation, energy conservation water conservation, material conservation' into planning and design
Beijing Capital International Airport (China)	Reduce energy consumption of air conditioning and lighting by using advanced technology and materials

In 2007, the Civil Aviation Administration of China brought up the concept of green airport for the new Kunming International Airport, then the concept of green airport begin to be prevalent in the Chinese civil aviation industry. The new Kunming International Airport demand all design units reflects green airport in the general planning, engineering design, etc. However, most of the policies and measures of environmental management of airport in China are limited in solving environmental problems after pollution. It has not established the life cycle environmental management system framework of civil transportation airport projects in China. Based on the successful experience of civil transportation airports of China, this paper will put forward the life-cycle environmental management system framework of civil transportation airport is put forward.

2. Literature Review

There are also many researchers researched several related studies of airport environmental management. Kılkış (2014) simulated Istanbul Airport to forecast the position of the airports and point out the importance of environmental influence analysis as well. He got more knowledge of the influence of the terminal energy consumption and which elements played a decisive role in carbon emission by analyzing the energy of terminal. Bartels, Muller and Vogt (2013) interviewed residents around Cologne Bonn Airport about the satisfaction of the airport by phone survey, and the results showed that residents around the airport hold the trust that administrators will improve the living environment by taking some measures. Bartels, Márki and Müller (2015) pointed out that the noise figure of planes was not only considered about outdoor sound pressure level, the number of planes was also concerned. And this conclusion had a certain referential significance of how to reduce the noises. Duinkerken, Selderbeek and Lodewijks (2013) revealed that single engine glide, operation pulling and electro-motor putting on aircraft wheels can all reduce the carbon emission of airport. Electro-motor method got the most obvious effect on saving the plane launch cost and carbon emission. Zheng, R. H., et al(2008) analyzed the features of airport environment influence factors to build an evaluation index system of airport environmental impact, meanwhile he also built a comprehensive evaluation matter-element model with multiple index and layers of the airport environmental impact based on matter element analysis theory. Shen Y. (1999) proposed four ways: airport management measures, airport engineering measures, plane measures and airport auxiliary measures to solve the airport noise problem, she then suggested the airport administrative department to build professional management organization and also bring in legislative regulation. Tang X.Y. (2008) put forward that Green Airport idea should be throughout every steps during the airport construction and operation process, and airport garbage harmless treatment as well as resource comprehensive utilization project were suggested to be put into effect. Li Longhai(2008) focused on power saving goal, used passive energy conservation design method to plan the airport site in an overall point of view combined with the airport energy consumption analysis, and then the airport adapted to the site environment to achieve the energy saving. He did energy-saving design to the airport terminal in every building design, and stated that there are two aspects in the concept of Green Airport: conservation and environmental protection.

3. Research method

This paper mainly involves the theory of environmental sociology, sustainable development theory, and green airport. Environmental sociology focus on research interactive relationship between environment and human society (Hong D.Y., 2009), so environmental management of civil transportation airport is one of the important researches of environmental sociology. Sustainable development theory was becoming a hot topic in the environmental field which required the span of environmental management extended to life cycle from the early stage to the operating period (Blewitt, J., 2014). The theory of green airport demand that comprehensive measure should be taken for keeping a harmonious coexistence of human being with the environment (The headquarter of Shanghai airport construction, 2010).

Based on the theory of green airport, environmental sociology and sustainable development theory, this paper have studied airport environmental regulations made by international civil aviation organizations and understood the airport legislation situations aiming to solve environmental pollution in countries around the world. We used the method of induction and extracted current situations to find effective practices which have been examined by applications in the past, combined with the regulations and practices of airports around the world, then they will be introduced into the effective environmental management system of civil transportation airport. Afterwards, the paper will put forward the life cycle environmental management system framework of civil transportation airport based on the practical experience of China large airport construction. This system can comprehensively and effectively improve the civil transportation airport environmental management status quo.

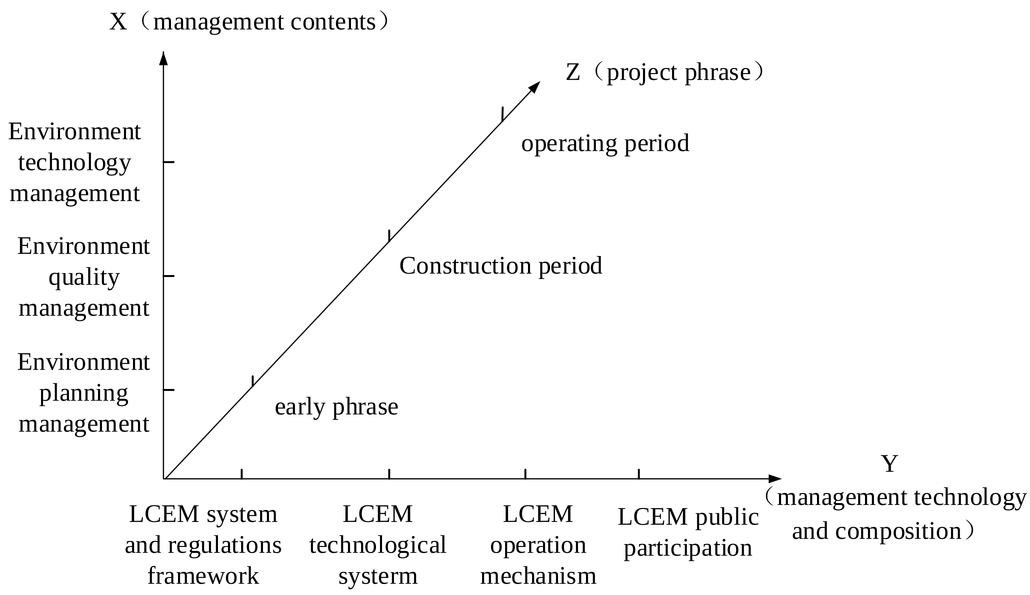

Fig. 1 The framework of the LCEM system of civil transportation airport

4. Life cycle environmental management framework of civil transportation airport

4.1 The part of life cycle environmental management framework of civil transportation airport

The life cycle environmental management (LCEM) system of civil transportation airport project includes three-dimensional space composed of X, Y, Z axis, as shown in Figure 1. The X axis shows three main environmental management contents of life cycle environmental management in the graph, the Y axis shows four management technology parts of environmental management in civil transportation airport construction project, and the Z axis represents three phrases of civil transportation airport project.

4.2 The introduction of life cycle environmental management framework of civil transportation airport

4.2.1 Project phase of life-cycle of civil aviation airport

The Z axis of the framework is divided into early phase of construction, construction phase and operation phase according to the whole life cycle. The national regulations and policies related to environment are mainly for regulating various behaviors in the life-cycle of civil transportation airport and limiting the activities which can cause damage to the environment quality, and then to achieve sustainable development of civil transportation airports. Because of the different pollution sources in three stages, the management of each stage is different. The pollution sources of each phase is shown in Table 2.

Table 2 Pollution sources in project phase of life cycle

Life-cycle of civil transportation construction	pollution sources	influence
Early phase	Environmental impact on the operation: determine airport location, traffic planning, airport design and planning, afforestation level	The planning and design phase does not produce pollution, but the results will affect the environmental management of construction and operation period.
Construction phase	(1) construction noise; (2) dust; (3) water pollution; (4) air pollution; (5) construction waste	Strengthen the relevant measures to control;
Operation phase	(1) great energy consumption; (2) low utilization of energy; (3) high maintenance costs; (4)great pollution;	Bring about main impact to the environment, which phrase the environmental management focus on.

4.2.2 Life cycle environmental management technology of civil transportation airport

The Y axis of the framework shows that the life cycle of civil transportation airport is classified by management technology and composition. The life cycle environmental management system of civil transportation airport construction project can provide comprehensive support and guarantee for protection work. The main contents of the whole life cycle environmental management system of civil transportation airport construction projects is shown in Table 3.

Table 3 Environmental management system of the whole life cycle of civil transportation airport

<table>
<tr><th>Phrase / Composition</th><th>Early phrase</th><th>Construction period</th><th>Operation period</th></tr>

</table>

Life cycle environmental management institution system and regulations framework of civil a transportation airport is a collection consists of environmental management systems, as shown in figure 2. It mainly include: the environmental impact assessment system in project planning phase and feasibility study phase; "three simultaneous" system, which mainly aims to put forward the requirements and regulations for hardware construction of environmental protection facilities; environmental protection acceptance system, aiming to implement the inspection and evaluation the environmental protection measures in whole processes (Deng T.J., 2009). Moreover, it also include three system which are studying and trying in China, name Environmental supervision system, aiming to manage the environmental behavior of whole construction process; Post environmental assessment system, mainly for the environment management of operation phrase, checking and review the environmental protection work before operation phrase; Public participation system, it means environmental protection needs the public participation in whole life cycle of the project so as to monitor the environmental management of all aspects and improve environmental management work.

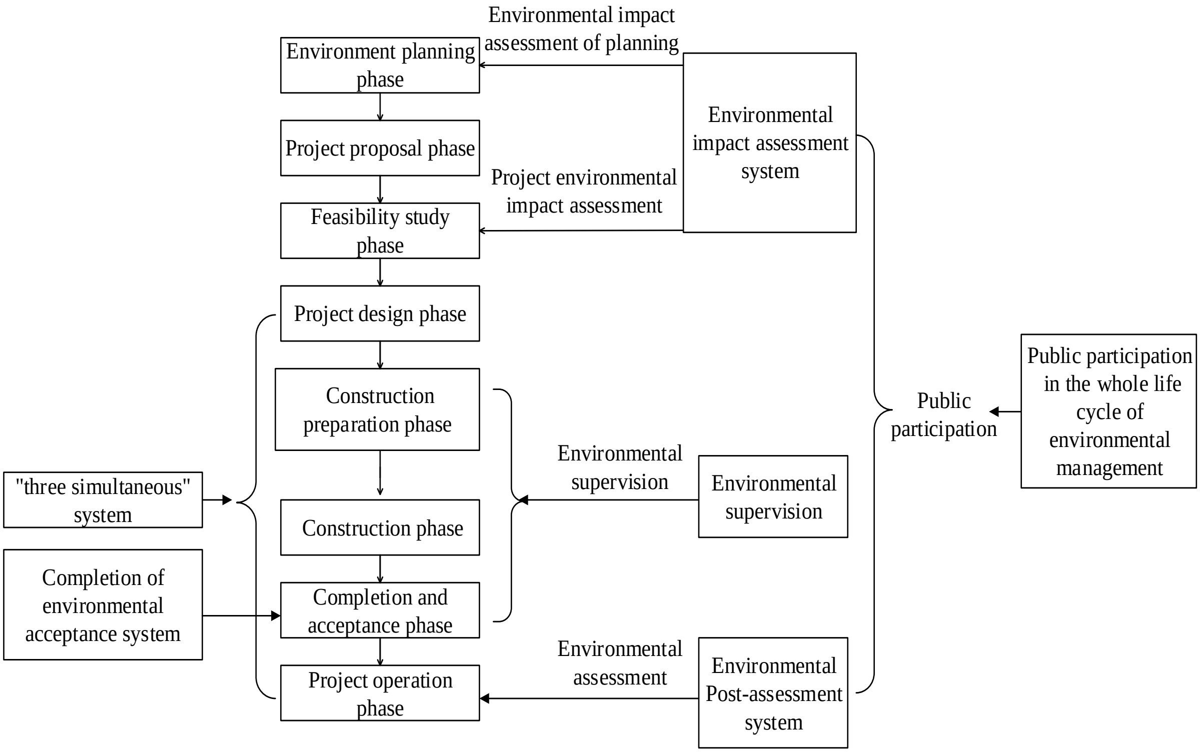

Fig. 2 Environmental management system of life cycle construction project

The establishment of life cycle environmental management technology and method system of civil transportation airport construction project is from the perspective of technical approach. In order to improve the existing environmental management techniques and methods of the civil transportation airport construction projects, such as the planning assessment, environmental assessment, environmental design and environmental protection acceptance and improve efficiency, we analyze the different environmental impact and management requirements. The effective use of the life cycle of environmental management techniques is conducive to the implementation of environmental protection measures.

Building the life cycle environmental management operation mechanism, mainly based on the ISO14000 environmental management system and ISO9000 quality standard management system, is an important component of the life cycle environmental management of civil transportation airport. This operation mechanism will cover the process from environmental policy formulation, environmental planning to operation, check and evaluation which can complete the environmental management process systematically accompanied with overall process prevention and punishment mechanism. Carrying out the life cycle environmental management operation mechanism in overall civil transportation airport construction project helps to build an international widely recognized, standardized, systematic environmental management paradigm.

Public participation method is another basic method of environmental management. Building the public participation mechanism and approach of raising the participation is the basic of this method. This method is an important institutional guarantee for reducing environmental decision-making errors, and perfected the content of life cycle environmental management system of civil transportation airport construction project.

4.2.3 The contents of life cycle civil transportation airport management

The X axis of the framework is classified by the management contents. The contents of life cycle environment management of civil transportation airport can provide the comprehensive content formulation and guidance for the environmental protection which promoted the comprehensive, perfection and validity of the environmental management. And the contents are reliable technical supports for the life cycle environmental management. The contents of life cycle environmental management of civil transportation airport was shown in Table 4.

Table 4 The contents of life cycle environmental management of civil transportation airport

Phrase / Contents	Early phrase	Construction period	Operating period
Environmental Technology Management	1. Reasonable site selection 2. Reasonable layout 3. Choose environmental friendly equipment and materials 4. Technology and system upgrade 5. Formulate rules for technology execution	Pollution prevention and technology control of construction	Pollution Abatement Technology (noise, air, land surface, solid waste, etc.)
Environmental Quality Management (QM)	1. Establish the quality index system 2. Environmental facility design 3. Develop environmental management system	1. QM of construction environmental factors (water, noise, air) 2. QM of construction environmental facilities (greening, health facilities, municipal facilities) 3. QM of construction environmental management	1. QM of operation environmental factors (water, noise, air) 2. QM of operation environmental facilities (greening, health facilities, municipal facilities) 3. QM of operation environmental management
Environmental Plan Management	Develop environmental policies and standards	1.Technical comparison and economic comparison 2.Cost optimization	1. Assessment and acceptance of results 2.Technology promotion

Environmental technology management study the method and system of technology management of the construction life cycle of civil transportation airport from the perspective of technology. The technology management is integrated management of technology and technological base of the environment protection. Effective environmental management of technology can improve the usage of environment technology and environment protection in the life cycle of civil transportation airport construction project.

Environmental quality management can be divided into quality management of environmental factors, quality management of environmental facilities and quality management of environmental management. Institutions and index system development are emphasized in the early stage of construction, and specific management quality evaluation is emphasized in construction stage and operation stage. Environmental quality management can improve the quality of the practice of environmental management, and can also contribute to the implementation of life cycle environmental management measures of civil transportation airport construction project.

Environmental plan management aim to improve the environmental management level on the experience and method aspects. Through developing policies to prevent in advance, optimizing in the process and post evaluation, environmental plan management provided experience accumulation and technical promotion at present and in the future for environmental management. It is also an important guarantee for reducing waste in the process of environmental management. And it can improve and perfect the existing environment management content.

5. Study on environment early warning of operating period of civil transportation airport based on gray system theory

The study on environment early warning of operating period of civil transportation airport can provide useful information for environmental management and improve environmental management level of civil transportation airport. Grey system theory is a kind of deepening and development of system thought. Grey forecasting model is a kind of short-term forecast tool, it can forecast the objects with raw data, and has higher prediction accuracy (Deng J.L., 2002). Modeling is based on the past and present known or unknown information, establish a GM model from the past to the future, to determine the trend of the future development of the system, to provide a basis for planning and decision-making. In this paper, the early warning of air pollution in civil airports, to a certain extent, shows regularity with the time change, and its index data has the character - small sample and poor information, so it is suitable to use gray system theory for early warning.

5.1 Selecting early warning factors

The environmental problems of civil transportation airport commonly include noise pollution, air pollution, water pollution, solid waste pollution and land use problems. The purpose of early warning is to provide support for decision-maker to develop solutions of environmental pollution. Typically, different environmental problem have different solution and different early warning system of environmental problem has similarity. So this section will only establish one warning system for one of the environmental problems. And the main purpose of this section is to discuss the feasibility of using the gray system theory in the environmental early warning of civil transportation airport, so in order to simplify study process, we select the concentration of NO_2 which is easily getting as the only early warning factors.

5.2 Defining the early warning standard

According to Chinese ambient air quality standards, we develop the ambient air quality standards and early warning standards, as shown in Table 5.

Table 5 Ambient Air Quality Standards

Pollutants	level	concentration limit mg/m^3 (standard state)			air quality	Warming level
		annual average	daily average	hourly average		
NO_2	grade I	<0.04	<0.08	<0.12	Good	-
	grade II	>0.04	>0.08	>0.12	Moderate	blue
	grade III	>0.08	>0.12	>0.24	lightly polluted	yellow

5.3 Establishing early warning model based on gray system theory

(1) The NO_2 concentration of 5 consecutive days of Shanghai Pudong International Airport is shown in Table 6. (If you want to predict for longer period, you can choose the three day or week average value of NO_2 concentration as basic date.)

Table 6 The NO_2 concentration of Shanghai Pudong International Airport

Date(Year 2010)	June 13	June 14	June 15	June 16	June 17
NO_2 concentration	0.103	0.109	0.117	0.116	0.121

(2) Building matrix based on gray system theory

According to grey prediction *GM (1, 1)* model,

$$B = \begin{pmatrix} -\frac{1}{2}[x_1(1) + x_1(2) & 1 \\ -\frac{1}{2}[x_1(2) + x_1(3) & 1 \\ \cdots & \cdots \\ -\frac{1}{2}[x_1(n-1) + x_1(n) & 1 \end{pmatrix} = \begin{pmatrix} -0.106 & 1 \\ -0.1645 & 1 \\ -0.2225 & 1 \\ -0.283 & 1 \end{pmatrix},$$

$$Y_n = [x_0(2), x_0(3), \cdots x_0(n)]^T = [0.109, 0.117, 0.116, 0.121]^T.$$

Then according to the formula "$\hat{a} = [a, u] = (B^T B)^{-1} B^T Y_n$", we can get the value of a and u and establish the early warning model.

(3) Calculating

Due to the complexity of the calculation, we use the computer software 'math tool' to carry out the calculation. Sort out the calculation results to form and calculate absolute error and relative error, as shown in Table 7.

Table 7 relative error and the average of relative error

date	actual value	predictive value	absolute error (residual error)	relative error
June 13	*0.103*	*0.103*	*0*	*0*
June 14	*0.109*	*0.1106*	*-0.0016*	*-0.01468*
June 15	*0.117*	*0.1139*	*0.0031*	*0.026496*
June 16	*0.116*	*0.1174*	*-0.0014*	*-0.01207*
June 17	*0.121*	*0.121*	*0*	*0*
average	-	-	-	*0.011*

5.4 Model precision verification and prediction results analysis

According to the relative error of residual error, we can easily figure out the posterior error C = 0.0021. According to the precision requirement of the grey system theory, the established early warning model is qualified when the posterior error C is less than 0.5. So the early warning model can objectively reflect the dynamic changes of air quality. In other word, the model can be used to predict the value of air quality index.

We can predict the NO_2 concentration of June 18 to June 20 through the early warning model. The prediction results are shown in Table 8.

Table 8 Prediction results

Date	June 18	June 19	June 20
NO_2 concentration	0.1247	0.1285	0.1324

Through the prediction results in Table 6, we can know that the NO_2 concentration is greater than 0.012 and less than 0.024 from June 18 to June 20. So the air quality is moderate according to the Table 3, and the warming level is blue. And the prediction results proved that using the gray system theory in the environmental early warning of civil transportation airport is feasible.

6. Conclusions

According to the problems of environmental management in the development of civil transportation airport, this paper puts forward the life cycle environmental management system from the perspective of practice and specifies the system need to include environmental management content dimension, life cycle dimension and management technology dimension. And then the early warning system of operating period of civil transportation airport based on gray system theory is established and proved feasible through a simple case. The results of this paper can provide the theoretical basis for the life cycle environmental management of civil transportation airport and contribute to solve the existing problems of environmental management of civil transportation airport. The study in this paper has a great significance for the development of civil transportation airport in the environmental protection.

Email: fernanda.ferrari@usp.br

Abstract

The Brazilian public bank described herein, Caixa Econômica Federal, is essentially a financial institution, which has also historically maintained a technical department comprising more than two thousand civil engineers and architects. These professionals perform technical feasibility analyses of infrastructure and housing projects that apply for public financing. Due to this peculiarity, this public bank is one of the most important stakeholders in the Brazilian Architecture, Engineering, Construction and Operations (AECO) industry. Currently, the project analysis process is manual, paper-based, time and labour consuming. Facing this situation, the institution has established tasks likely to be automated through BIM (Building Information Modelling), and is now pursuing its adoption. Since there are not official modelling standards in Brazil, establishing them was deemed necessary to enable a BIM-based project analysis in a near future. The aim of this paper is to analyse the proposed innovation through a discussion group that has experimented modelling with the guidelines and tools proposed by the bank. The purpose is to determine whether the proposition is viable and if future users will be willing to adopt it. Although the evaluation of the tools and project template proposed were positive, the results showed a broader issue of segregation between the disciplines of design and cost estimation. Those results may influence not only the acceptance of the technological innovation proposed by Caixa, but BIM adoption in Brazil in general.

Keywords: BIM, Feasibility analysis, Standardization, Modelling Guidelines

1. Introduction

Caixa Econômica Federal (Caixa for short hereafter) is a Brazilian public bank leader in financing construction and in transferring federal resources for public infrastructure and social housing. It holds a 67.7% share of the Brazilian housing financing market, which reached US$ 127.81 billion[1] in 2014. The public infrastructure portfolio, which enables investments in the fields of urban mobility, energy, logistics, sanitation and others, presented a total balance of US$ 21.33 billion

---

[1] The conversion rate applied was US$ 1.00 = R$ 2.6587 (current exchange rate in December 2014).

in 2014, an increase of 52.8% compared to the previous year, and a total volume of new contracts of US$ 12.52 billion (Caixa Econômica Federal, 2014).

The institution currently has 97,900 employees, and over 2,000 of them are engineers and architects, working in 74 regions in the country. Since there is a significant deficiency in construction and building regulation control in Brazil, the institution has been playing an important role performing technical feasibility analysis and verifying projects' suitability. Caixa is a notable improvement driver in the Brazilian civil construction industry through its requirements for project financing. An example is the demand that all low-income and social housing construction companies must be certified by the Brazilian Program for Housing Quality and Productivity (PBQP-H) (Ministério das Cidades, 1998).

The main objective of the technical department is to analyse the operations to ensure that the resources are correctly applied. Therefore, the work is dictated by a strict set of rules that are based on laws, public procurement regulation and demands by federal investments funds. A technical analysis of proposals verifies their compliance with the funding program guidelines, the suitability of the design to the intervention site, its functionality and technical feasibility, all combined with a verification of cost and schedule.

Currently, the analysis process is manual, paper-based, time and labour consuming. All documents are provided on paper, in an extremely bureaucratic process. The design is manually checked, and the most time-consuming task is the quantity take-off for comparison with the proposed budget. Facing up to this situation, the bank has established tasks likely to be automated through BIM (Building Information Modelling), and is now pursuing its adoption (Ferrari and Melhado, 2015). Automated design checking and cost checking are the two most critical activities and the latter was chosen to start the adoption of BIM by the institution.

Since BIM adoption rate in Brazil is low (McGraw Hill Construction, 2014), and there is not a national guide or reference for BIM-based design in Brazil, the institution believes that it is essential to provide modelling guidelines and tools in order to obtain project files adequate for analysis.

The aim of this paper is to analyse the proposal being developed for modelling guidelines and tools, considering that, if approved, it has the potential to become a national standard. The research method applied is the proposition of a structured exercise using the suggested Revit project template and two plug-ins, followed by a discussion group and a questionnaire. The purpose is to determine whether the proposition is viable and if future users will be willing to adopt it.

2. Research Context

2.1 Caixa Econômica Federal as a Policy Maker

In 2013, McGraw Hill Construction (2014) conducted a research that pointed out that 55% of the Brazilian contractors declared to have low BIM engagement, 70% claimed to have been using BIM for no more than two years, and 75% stated that less than 30% of their projects are in BIM. These data indicate that Brazil was still at an initial level of BIM adoption.

Referring to Succar's BIM Capability Stages (Succar, 2010), the Brazilian Architecture, Engineering, Construction and Operations (AECO for short hereafter) Industry is pursuing BIM Stage 1, which is object-based modelling. Caixa Econômica Federal is considered in this paper as a *Policy Maker* (Succar and Kassem, 2015) due to its potential to disseminate standards, regulations, guidelines and best practices throughout the AECO Industry, therefore playing an important role in the diffusion of this new technology.

Although this Brazilian public bank has the prerogative to be a coercive and normative stakeholder, pressuring a top-down diffusion (Succar and Kassem, 2015), it has first adopted a passive approach, which consists, as Succar and Kassem point out, in making others stakeholders aware, encouraging and observing BIM adoption.

The institution acknowledged that the absence of modelling standards, guidelines and regulations would be a major barrier for any technological innovation in this area. Therefore, the efforts are towards providing tools and guidelines to the AECO Industry to allow a BIM-based project analysis, in a near future.

2.2 Guidelines and tools proposed

The proposal analysed herein was developed by a consulting company initially to solve an internal problem caused by restructuring in the National System of Costs Survey and Indexes of Construction (SINAPI for short hereafter), which is maintained by the institution and adopted by the government for public works budgets. Cost components were recently revised to consider more accurate rates of productivity (Oliveira et al., 2014), resulting in greater difficulty in choosing the correct cost component for each budget item. For example, a masonry wall that was previously associated with just one cost component now has its costs subordinated to the length of the wall, the existence of openings and to the type of mortar mix (mechanical or manual).

A project template and two plug-ins were developed in order to assist the cost estimator in choosing the right budget component for each design object, by filtering the options based on modelled characteristics or imputed information to the design. Revit was chosen due to its large diffusion in the Brazilian AECO Industry.

Firstly, to ensure standardization, a project template was conceived including loaded families and defined settings in order to provide a starting point for new projects (Autodesk, 2015). Thus, it is guaranteed that the data used in the model have the characteristics necessary for the proper functioning of plug-ins.

Secondly, two plug-ins were developed for Revit. One of them helps creating wall coverings as separated walls, so the designer is able to easily define different characteristics for each (wall plug-in hereafter). Through this application, the user chooses a room to establish settings and select from a list of coating materials (pre-determined in the template) defining its height and thickness. The plug-in automatically creates a separate wall element for each coating layer attributed, which subsequently facilitates its handling and quantification.

Finally, another Revit plug-in (SINAPI plug-in hereafter) was developed to assist the specification of materials and components for each element modelled, relating them to a SINAPI cost element. As shown in Figure 1, in each room it is possible to select materials filtering possibilities according to the characteristics of the modelled object and enabling to export data to finalize the budgeting process.

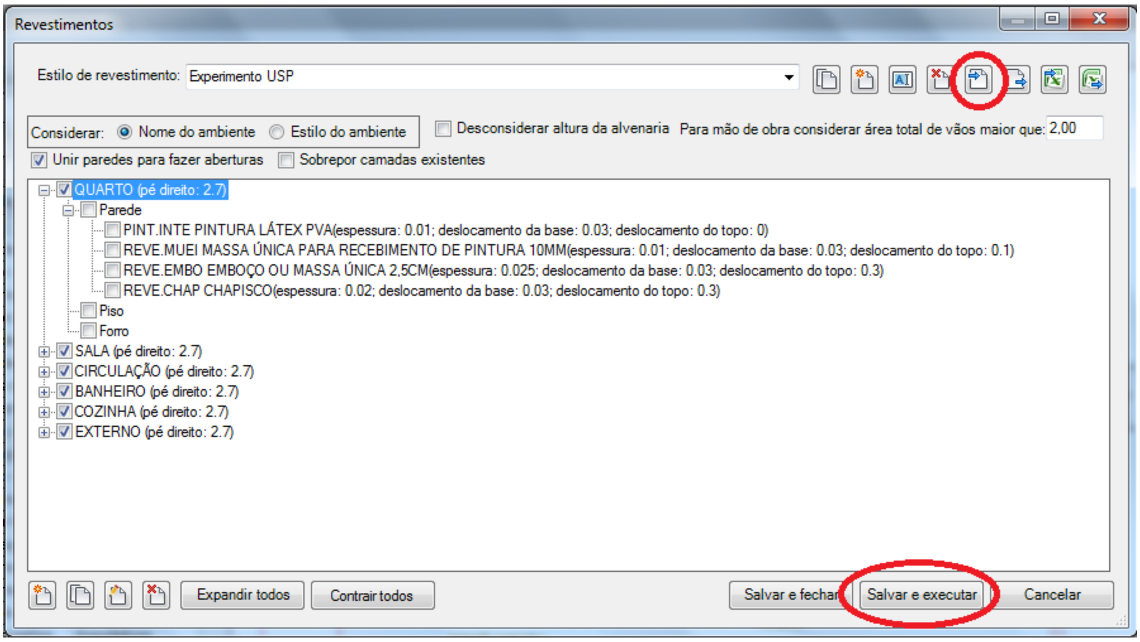

Figure 1: SINAPI plug-in

3. Methodology

The benefits of BIM utilization are not yet established clearly and empirically; thus the decision of adoption is often based on speculated benefits (Barlish and Sullivan, 2012). Consequently, verifying the user's behavioural intentions towards the proposed technological innovation was considered important.

The research method applied was a group discussion in which a modelling exercise was proposed, followed by a structured and supervised discussion among the participants, and finally, at the end of the oral discussion, the participants answered a small questionnaire. The purpose was to encourage a widespread debate among research participants, thus verifying the real applicability of the proposed tools and project template.

The modelling exercise was developed so that the proposed project template and plug-ins would be employed in a real situation. The exercise consists in modelling a small house, applying its components and materials, and lastly creating a construction budget by choosing a cost component from SINAPI for each element of the model (Figure 2).

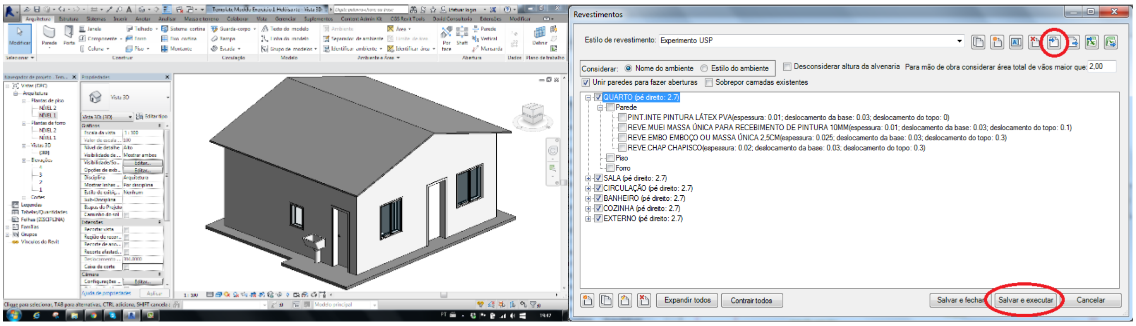

Figure 2: Screen capture of the exercise

To make sure that they would employ the tools correctly, a specialist guided the participants throughout the exercise. All the notes and questions were recorded along with their comments during the guided discussion.

Ten AECO professionals attended the workshop and they had a diversified profile, as seen in Table 1:

Table 1: Workshop participants profile

Participant #	***Educational Background***	***Occupation***	***Company***	***BIM Experience (Projects)***
1	*Architecture*	*Coordinator of the BIM Modelling Group*	*Company 1*	*More than 10*
2	*Civil Engineering*	*Civil Engineer*	*Company 1*	*More than 10*
3	*Undergraduate*	*Draftsman*	*Company 2*	*More than 10*
4	*Civil Engineering*	*Construction Manager*	*Self-employed*	*1-3*
5	*Architecture*	*Revit Instructor and Consultant*	*Self-employed*	*More than 10*
6	*Architecture*	*BIM Manager*	*Company 3*	*1-3*
7	*Architecture*	*Architect*	*Company 3*	*1-3*
8	*Architecture*	*Architect*	*Company 3*	*1-3*
9	*Electrical engineering*	*Electrical System Designer*	*Self-employed*	*None*
10	*Civil Engineering*	*PhD Candidate*	*Academic*	*None*

The workshop had an open invitation, and there were no fees collected. Having some experience with BIM was preferred but not mandatory to the participants. Their miscellaneous background enriched the discussion in which various points of view were available (Figure 3).

Figure 3: Workshop presentation (photo by the authors)

Besides spontaneous comments during the presentation and the exercise, the researchers proposed an open discussion about the points listed below.

- While modelling, what were your impressions regarding:
    - Difficulty and time to build the model?
    - Model visualization?
    - Differences from your own modelling practices?

- While using the wall plug-in and the SINAPI plug-in, what were your impressions regarding:
    - Operation of the plug-in?
    - Benefits of the plug-in?
    - Plug-in applicability in your daily practices?

The results shown herein are a compilation of the registration forms and questionnaire answers, in addition to a careful analysis of the discussion and questions from participants, recorded by the researchers.

3.1 Limitations

Even though the research method was satisfactory to investigate the main purpose of this article and to promote a broad discussion of the proposed object, it imposed a limited number of participants. There was an effort towards gathering a diverse group, but the possible influence of subjective views from the participants was taken into consideration in the final analysis.

4. Research Data

4.1 Participants profile

According to the information extracted from the registration forms and questionnaire, Architects and Civil Engineers were the majority in a young and well-educated group where at least half of the participants were postgraduates and under 30 years old (Figure 4).

The most popular BIM uses among the participants is for design coordination, visualization and presentation, quantity take-off and construction planning. Although most of them have some professional experience with construction cost planning, only three of the participants have already used a BIM software for this purpose, and they declare to be using Revit.

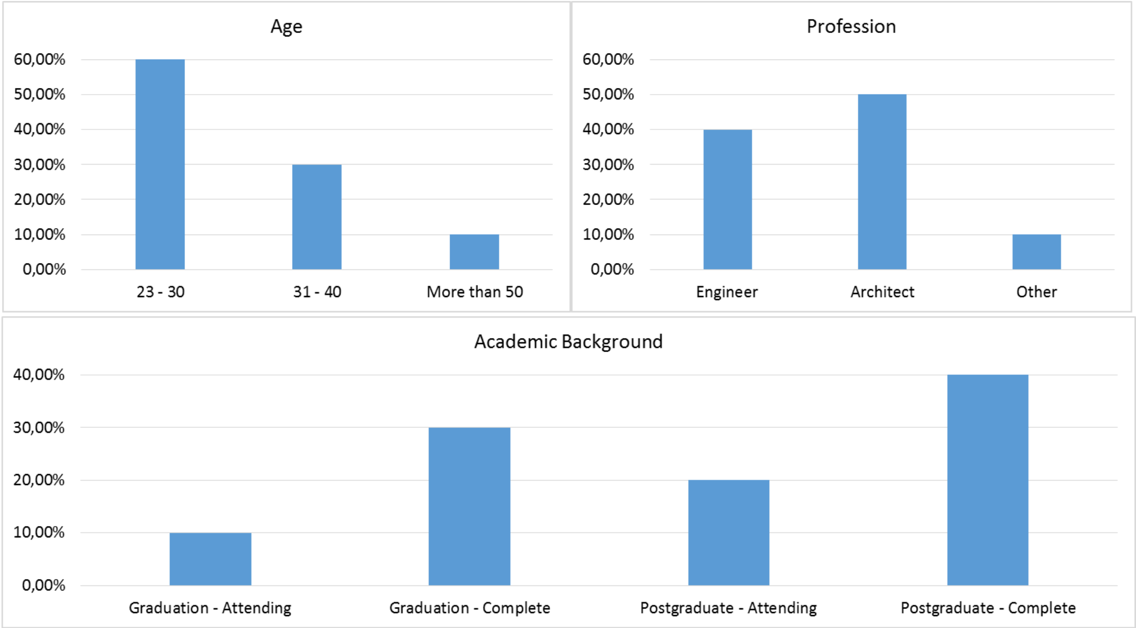

Figure 4: Participants profile

4.2 Motivations

The motivations for employing a BIM software for cost estimation noticed during the discussion were essentially related to innovation in design practices and for reducing cost estimating complexity. The changes in designer's responsibilities with the adoption of a BIM-based design process were found to be a major concern, since some decisions related to construction planning, cost estimation and construction processes must be taken earlier in the project.

Some participants admit to neglect cost planning in the design process, and they recognize that there is a lack of integration between design and cost estimating.

When asked, all the participants agreed that if Caixa established a modelling standard, they would adopt it.

4.3 Benefits

The questionnaire results showed that most participants (88 to 100%) agreed that, compared to their current practice, it was easier, faster and more accurate to model, to extract quantities and to estimate project costs in the exercise (Figure).

There were also positive responses to the questions regarding the intention of use, suitability and perception of usefulness to their professional practices (Figure 6). During the discussion, it was pointed out that the wall plug-in would be very applicable to buildings with repetitive elements such as hotels, for example. In addition, most participants declared that it was easy to accomplish the exercise.

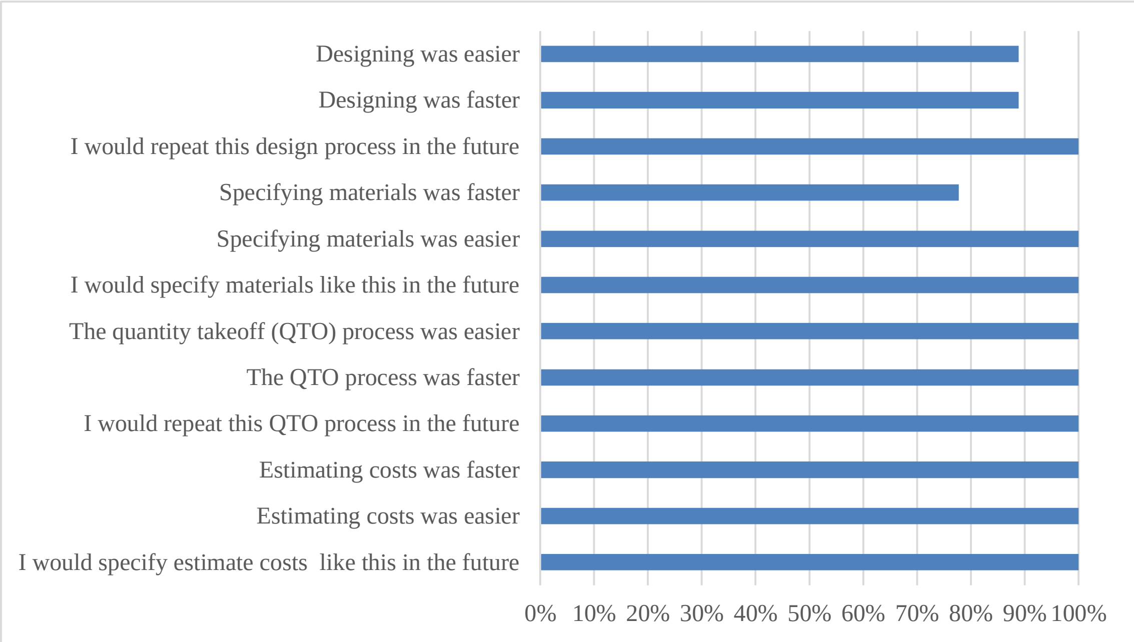

Figure 5: Results in scale from 0 to 100% for agreement with statements about the design and cost-estimating process using the tools and guidelines proposed

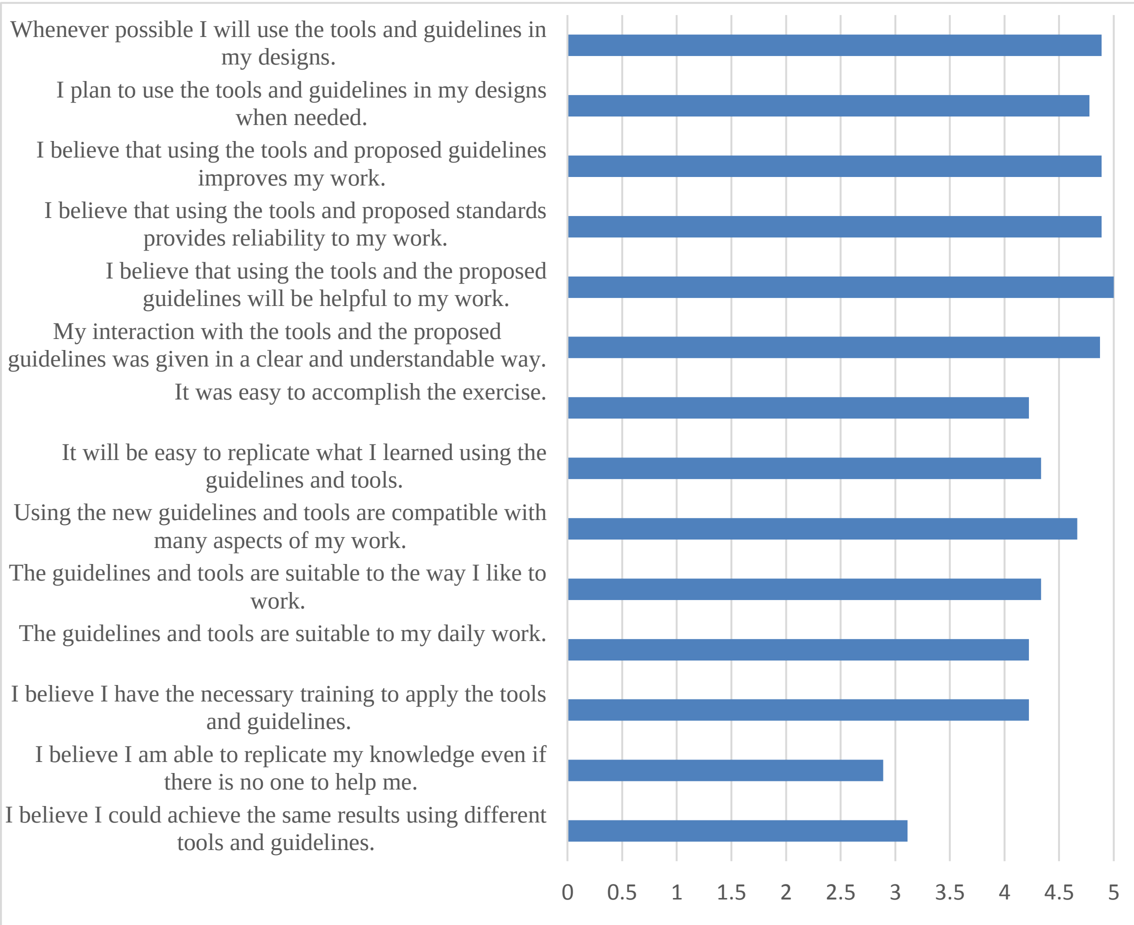

Figure 6: Results in scale from 0 to 5 for agreement with statements about use of tools and guidelines

4.4 Difficulties

The main barrier acknowledged by the researchers was perceived during the exercise explanation, evidenced by the questions the participants were asking. Their inquiries reflected their unfamiliarity with construction processes, which lead to great difficulty in estimating costs. Furthermore, the participants appeared uninformed about SINAPI’s structure and guidelines, asking elementary questions about it.

About the plug-ins and project template proposed, some participants reported difficulties in designating objects specification with the SINAPI plug-in due to the various options it presents, making it evident that the filtering process of materials and components available should be more accurate. They also expressed some concerns about exporting the data to other cost-estimating software.

Ultimately, although the participants approved their training, they declared they would have some difficulty in reproducing what they had learned without any help.

5. Analysis

The modelling guidelines and plug-ins proposed can be considered approved, almost unanimously, with minor suggestions for improvement. The TAM (Technology acceptance model) postulates that a user's behavioural intention to use technology is related to the usefulness and ease of use perceived (Son et al., 2015), and the results indicate that the participants pointed out these qualities in the proposal.

However, it should be taken into consideration that most participants are comparing the proposed practices with non-BIM traditional methods. This fact can partially explain why some participants believe that they could achieve the same results using different tools and modelling guidelines: it is due to their interest in a BIM-based practice rather than a specific tool. The lack of modelling experience can also explain why they believe they could not reapply the exercise without help.

The results also called attention to the fact that design and cost estimating are segregated disciplines, and the professional responsible for the design is not always aware of the entire construction process, including the specification of materials and cost components. That is a major barrier, not only to the acceptance of the proposed tools and guidelines presented in this paper, but essentially to a BIM-based design and cost estimation practice (Gu and London, 2010).

6. Conclusions

Even though Caixa is a financial institution, it is also an important stakeholder in the Brazilian AECO industry and can be considered a policy maker due to its potential to disseminate standards, regulations, guidelines and best practices. Therefore, its efforts towards establishing modelling standards should be closely monitored because of their likelihood of becoming Brazilian national standards.

The aim of this study is to analyze the tools (plug-ins) and project template in development, which are based on modelling guidelines proposed by the institution. For this purpose, a modelling exercise was proposed followed by a group discussion and a questionnaire to identify users' behavioural intentions towards the proposed technological innovation.

In spite of the focused purpose of the research, and the positive assessment of the plug-ins and project template, the results revealed a broader issue of segregation between the disciplines of design and cost estimation, evidenced in the difficulty demonstrated by the participants during the exercise. That may influence not only the acceptance of the technological innovation proposed by Caixa, but BIM adoption in Brazil in general.

Further studies should address this issue in terms of desirable professional qualification, responsibilities definition and impacts to the design process.

The continuity of this study will focus in the technical department of Caixa and the impacts of this technological innovation. Thus, analysing the organizational environment and the attitude of the employees in relation to the acceptance of change and innovation proposition.

A Framework of an Image-based Integrated Approach to Create As-Is Building Information Models for Existing Buildings

Qiuchen Lu and Sanghoon Lee

Department of Civil Engineering, University of Hong Kong, Hong Kong
Email: u3003601@connect.hku.hk

Abstract

Building Information Modelling (BIM) provides an intelligent and parametric digital platform to support activities throughout the life cycle of a building and has been widely used for new building construction projects. However, most existing buildings today often do not have completed as-is information documents, nor existed meaningful BIM models. Despite the growing use of BIM models for relatively new buildings and the improvement in as-is records, incomplete or even incorrect information is still one of the main reasons for the low-level efficiency in facilities management. Furthermore, as-is BIM modelling for existing buildings is considered to be a time-consuming and expensive process, which requires great effort, time and skilled workers. Hence, developing an efficient way to create an as-is BIM model would be essentially the foremost step for effective operations and maintenance of existing buildings in their life cycle using cutting-edge BIM tools. We aim at developing a framework to establish a high efficient as-is BIM modelling system that integrates diverse building data in different formats (e.g., photo images, drawings, text data) with low cost, in order to improve efficiency and effectiveness of operations and maintenance, and furthermore possibly support refurbishment of a building. With this ultimate goal, this paper focuses on analysing state-of-the-art object recognition and reconstruction methods applicable for creating as-is BIM models, and summarises merits and limitations of these existing techniques and methods. Then, a framework is established with the most suitable methods on the basis of applying image sources and existing documents of the target building. The framework mainly includes a mechanism that supports automated creation of as-is objects with their meanings and information, and an assisting information library for the target building. The mechanism will use intelligent reasoning algorithms as appropriate such as the hybrid neuro-fuzzy algorithm in order to take into account possibilities of information shortage. The information library will mainly consist of four functional modules and four information modules (i.e., surface information, geometric representation, extracted information, and features information). Furthermore, key challenges and current progress are also addressed in this paper.

Keywords: as-is BIM model, hybrid neuro-fuzzy algorithm, information library, operations and maintenance

1. Introduction

On January 29, 2010, building collapse accident suddenly happened in Ma Tau Wai road, Hong Kong. An old six-story walk-up building suddenly crumbled at about 1:30PM. Four people died. Reasons for those accidents were often related to inefficient operations and maintenance (O&M) of facilities using traditional methods. With the increasing complexity of buildings in recent years, facilities management need a wide range of activities and building information associated to perform the activities. Hence, efficiently accessing to up-to-date information required for operating and maintaining a facility is essential and vital. Consequently maintaining the information up-to-date throughout the lifecycle of the facility is thus one of the most important tasks in O&M phase. The current situation, however, is that most existing buildings have only 2D drawings and text documents in a hard-copy format and/or in an electronic CAD format. These documents may not keep updated in time in the O&M phase. Thus, missing or incorrect building information would lead to inefficient decision making processes, which could cause significant delays in responding occupants' daily requests and emergencies. There is an urgent need of effective ways to manage all the information in the O&M phase.

Building Information Model (BIM) has been proved to be an intelligent and parametric digital platform and could support activities throughout the life cycle of a building, including facilitating design, construction, and operations and maintenance of facilities. According to the McGraw hill Construction's investigation of BIM in more than 10 countries, including North America, Europe, South Korea etc., the percentage of projects implemented with BIM increases sharply from an average of 39% to over 69% from 2013 to 2015 (McGraw Hill Construction 2014). It is proved that BIM has been widely used for new building construction projects, such as design authoring, existing conditions modelling, maintenance scheduling, and disasters planning (Kreider et al. 2010).

However, although the concept of BIM as a "database that stores, links, extracts and exchanges information", presents a promising BIM use for operations and maintenance of facilities, the lack of effective methods to reconstruct BIM for an existing building has prevented stakeholders' interest in using BIM data to support the O&M phase. They cannot fully utilize BIM technologies and get the most benefits. Furthermore, current methods and technologies of constructing as-is BIM models mainly depend on human effort. It is considered to be a time-consuming and costly process, and even sometimes reconstructing the as-is BIM model may be treated as a meaningless task and counteract benefits for civil infrastructure projects (Forns-Samso 2011; Lee and Akin 2009).

Nowadays, considering the extra effort and time of the reconstructing process, focuses have been mainly on developing effective and automatic/semi-automatic methods to address these problems. However, it is still a long way to achieve automated and highly efficient creation of as-is building information model for existing buildings. To reach this objective, we reviewed previous efforts in details, and merits and limitations of these existing techniques and methods are summarized (Chapter 2). Then, a novel framework of reconstructing as-is BIM models is established with the most suitable methods on the basis of applying image sources and existing documents of the target building (Chapter 3). Furthermore, our research progress and feasibility analysis of this framework is presented and discussed in this paper.

2. Literature Review

2.1 Overview of Fundamental Image Processing Methods and Image-based Building Reconstruction Approaches

Beginning with the Moravec (1981) corner detector, researchers began to keep an eye on image processing and make effort on matching up the geometric primitives (e.g., corners, edges) of the 2D images. Since then, researchers has tried to extract information from images and keep developing more reliable and stable functions as shown in Table 1. Inspired by local image descriptors, Lowe (2004) presented the Scale Invariant Feature Transform (SIFT) in 1999. This SIFT descriptor translated and detected image local features into scale-invariant coordinates for image processing. After that, Mikolajczyk and Schmid (2005) introduced an extended descriptor based on SIFT, which was the gradient location and orientation histogram (GLOH). This robust image descriptor improved the SIFT by changing the location grid and replying on principal component analysis (PCA) to reduce the size of images. This descriptor could outperform both SIFT and PCA-STFT, but it was relatively expensive from a computational perspective. An approach introduced by Bay et al. (2008) could be treated as a detector and descriptor for image matching. They developed Speeded-Up Robust Features (SURF) for object recognition and 3D reconstruction. This novel detector-descriptor scheme was inspired by the leading existing detectors and took advantages of them. It was proved to be an effective tool in feature extraction (Bay et al. 2008). The aforementioned methods review the fundamental methods. As shown in Table 1, researchers have applied these methods in image processing, interest point detection, object recognition, image matching etc. These methods (e.g., SIFT/SURF) are always set as the basic step of an image-based recognition and reconstruction system.

Referring to Table 1, image-based building reconstruction approaches are divided into feature representation-based approaches, wide baseline matching-based approaches, dimensionality reduction-based methods, clustering-based algorithms and others (reconstruction of image-based 3D point cloud model). The first approach mainly focuses on the process of feature extraction. The second approach relies on matching corresponding feature points between the query image and a reference image. The third approach eliminates features and enhances the efficiency by reducing the feature into a much lower dimensional subspace, and the fourth approach tries to group those image structures into different clusters by researching on their different relationships. Typical examples representing each approach are listed in Table 1. In addition, there is another image-based technology commonly used in the computer vision community. It can be used for creating 3D point clouds of the target building from a collection of overlapping images. Hence, it provides the possibility of 3D point cloud reconstruction from a set of images instead of laser scanners. One of the methods that are most commonly used in various industries is the Structure from Motion (SfM) (Wu 2013).

Table 1: A brief summary of the typical fundamental image processing methods and image-based building reconstruction approaches

	Classifications	*Different algorithms*	*Equation / literal expression*
Fundamental image processing methods	*Corner detection*	*The Moravec corner detection algorithm*	*The earliest algorithm, which measured each pixel in the image, relied on similarity to decide each corner.*
		The Harris&Stephens / Plessey / Shi–Tomasi corner detection algorithm	*This algorithm improved the Moravec corner detector by implementing the differential of the corner and the local auto-correlation function.*
		The Förstner corner detector	*This detector provided an approximate solution, which intended to find the point (x_0) closest to all the tangent lines of the corner.*
		The curve curvature corner detection algorithm	*This algorithm is suitable for an image edge existing large curvature.*
		An affine invariant interest point detector	*It was based on the multi-scale Harris detector and used the second moment descriptor with non-uniform Gaussian kernels.*
	Key-Point extraction /Feature descriptor	*The Scale Invariant Feature Transform (SIFT)*	*The SIFT descriptor will depend on character of the target image aiming at deciding a group of images as references. And then, in the light of the Euclidean distance of feature vectors, the target image would confirm the exact one from these entire candidates.*
		The gradient location and orientation histogram (GLOH)	*The GLOH is a SIFT-like descriptor, which considers spatial regions for the histograms and uses PCA to reduce higher dimensionality.*
		Principal Component Analysis (PCA)–SIFT	*Steps of the PCA-SIFT descriptor follow: (1) compute the local patch eigenspace for expressing the gradient images; (2) compute its local image gradient; (3) derive the compact feature vector for image matching.*
		Speeded-Up Robust Features (SURF)	*This SURF is achieved by relying on integral images for image convolutions and using the Hessian matrix-based measure and a distribution-based descriptor.*
	Line extraction	*The steps of processing: Edge detection; Edge thinning; Edge linking; Line fitting; Unsuccessful line segments cleaning; Corners connection.*	• *Edge detection (Sobel operator);* • *Edge thinning (Skeleton line extraction, Morphologic operators, Canny methods);* • *Line fitting to edges (Polyline composition or decomposition algorithm, Tolerance based algorithm, Hop-Along algorithm);*
Image-based building reconstruction approaches	*Feature representation-based algorithms*	*Examples: 1). The hyper-polyhedron with adaptive threshold (HPAT); 2). The steerable filter-based building recognition (SFBR); 3). The SIFT/SURF based approach;*	
	Wide baseline matching-based methods	*Examples: 1). The fast wide baseline matching algorithm; 2). The augmented reality-based navigation systems;*	
	Dimensionality reduction-based methods	*Examples: 1). The linear subspace methods (LSMs) (such as: principal component analysis (PCA) and linear discriminant analysis (LDA)); 2). The manifold learning algorithms (such as: locally linear embedding (LLE), isometric feature mapping (Isomap), Laplacian Eigenmap (LE));*	
	Clustering-based algorithms	*Examples: 1). Hierarchical building recognition (HBR) based on vanishing point detection and localized color histograms; 2). The sketch-based representation method; 3). Clustering-based landmark recognition method;*	
	Others	*Examples: 1). Reconstruction of image-based point cloud model: the range image-based reconstruction method based on the Structure from Motion (SfM);*	

** Chung et al. 2009; Goedemé et al. 2004; Harris and Stephens 1988; Kim et al. 2006; Li and Allinson 2013; Li et al. 2014; Lowe 2004; Mikolajczyk et al. 2002; Shao et al. 2003; Suleiman et al. 2011; Wu 2013;Lu and Lee 2015.*

Based on their contributions in image analysis, information mining and 3D geometry model reconstruction, many building recognition and reconstruction approaches have been further improved and tried to achieve fully-automated/semi-automated 3D reconstruction geometry models according to image sources. Furthermore, they are often treated as an essential step to create as-is BIM models for existing buildings.

2.2 Overview of Semi-automatic or Automatic Methods of Creating As-is BIM Models for Existing Buildings

As shown in Fig. 1, creating an as-is BIM model using different technologies can be divided into four main steps: 1) data capturing step in which various building surveying technologies can be chosen and raw data sets are collected; 2) data pre-processing step in which image processing methods are implemented and information is extracted; 3) object recognition step in which objects are classified into different groups and complemented by semantic information; 4) the as-is BIM models creation step in which each object's relationships with others are identified and the primary partial information model becomes a semantically rich BIM model. Semi-automatic or fully-automatic Creation of as-is BIM models requires to streamline the process, starting collecting initial inputs (e.g., images) and ending up with constructing an as-is BIM model, while the whole intermediate processes apply semi-automated or automated techniques. In order to optimize this process, a reliable, high efficient, low-cost and automated method for representing BIM models accurately is imperative nowadays. Many researchers have focused on this field (Brilakis et al. 2010; Díaz-Vilariño et al. 2014; Dimitrov and Golparvar-Fard 2014; Murphy et al. 2013; Nagel et al. 2009). For example, in order to simplify the overall process and to increase the flexibility and operability, a two-step BIM model construction process has been developed by Nagel et al. (2009). The creation process focuses on generating as-is BIM models from 3D geometry models. The intermediate layer uses CityGML building models. Furthermore, IFC (Industry Foundation Classes) building models also need to be created from CityGML. Since there are considerable gaps between the pure 3D geometry model and the as-is BIM model, it is difficult to achieve a fully automated creation process directly using this method. In addition, there are other limitations as well. For instance, the optimal and suitable data interpretation is still the essential concern (Nagel et al. 2009).

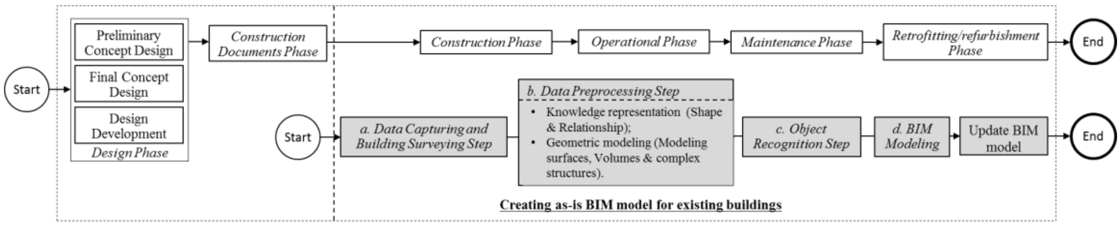

Figure 1: The as-is BIM model creating process for existing buildings in life cycle

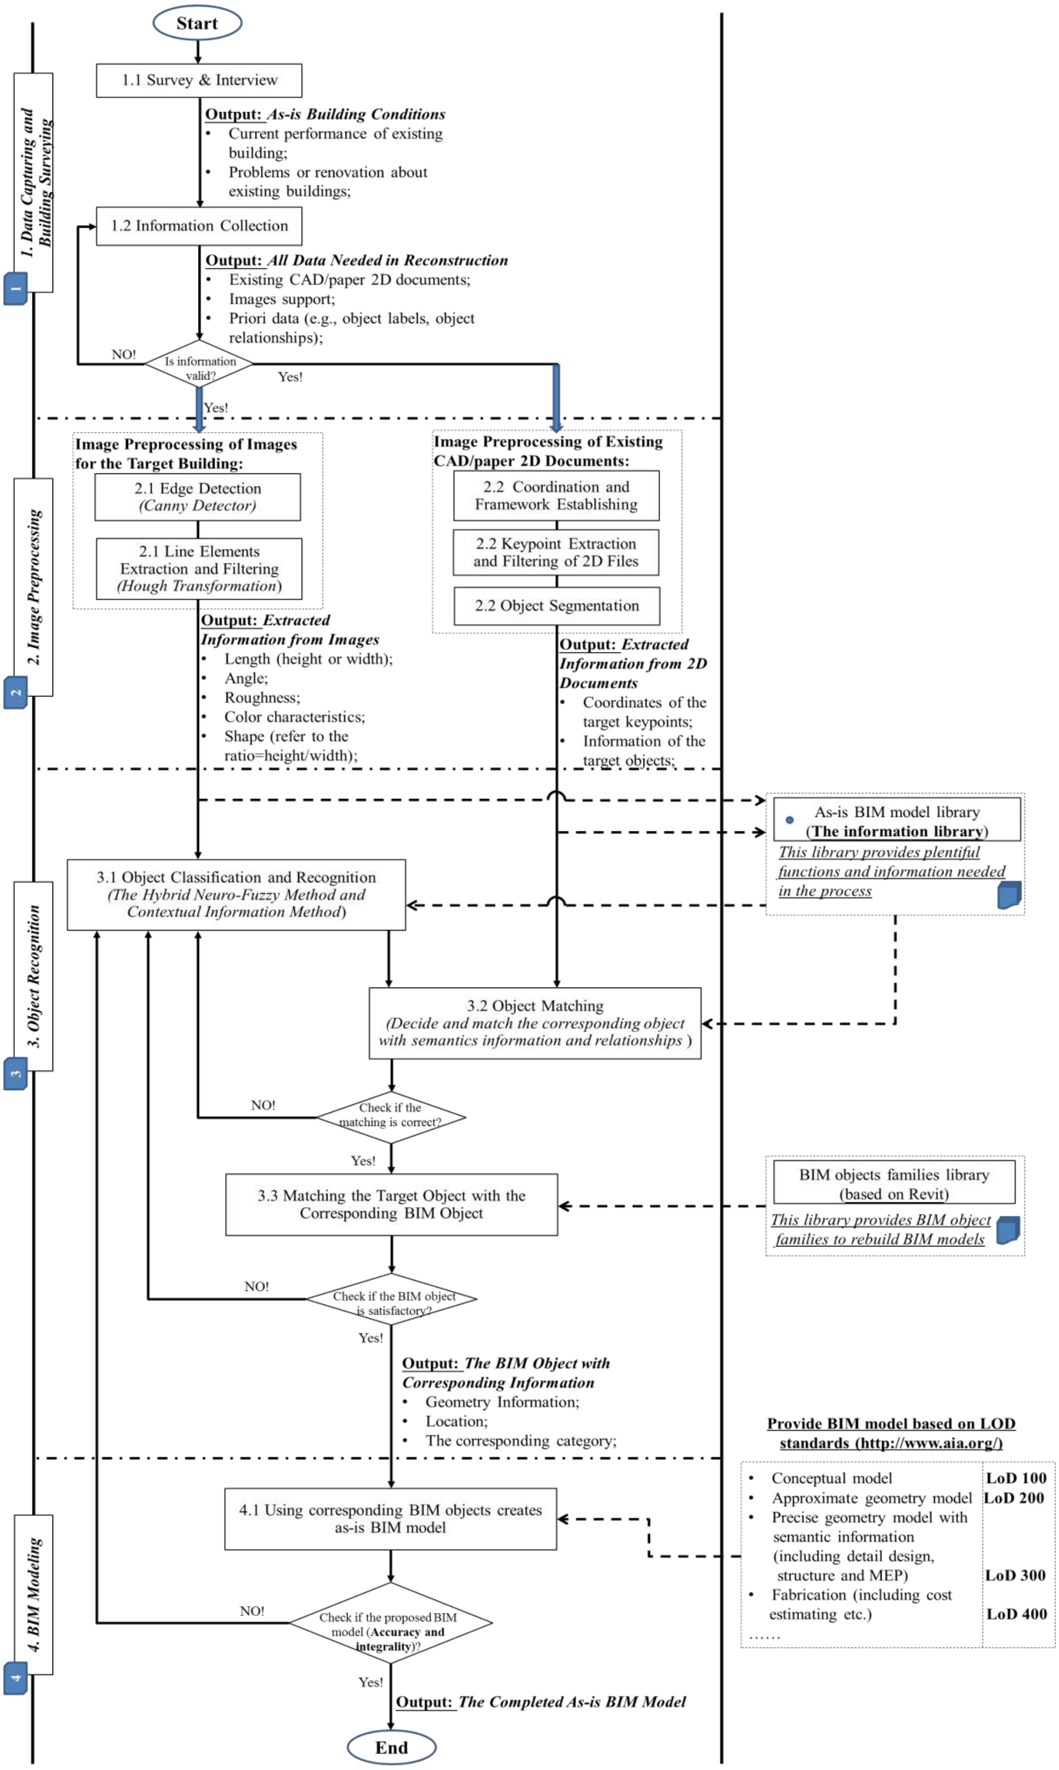

Figure 2: Framework of reconstructing as-is BIM model

3. Framework Description

We develop an innovative framework that aims to address the limitations of existing methods and to provide a high-efficient and low cost approach to create as-is BIM models for existing buildings, which does not require skilled workers. The framework chooses the image-based approach and implements corresponding computing technologies for existing buildings, as shown in Fig. 2. The framework includes four stages: data capturing and building surveying, data pre-processing, object recognition, and constructing as-is BIM models. The specific tasks to achieve each stage are stated as follows:

Stage 1: Data capturing and building surveying step.

This stage mainly focuses on collecting raw building data. The building data should cover all necessary existing documents (e.g., existing CAD documents, paper works and maintenance information) and images taken from the target building. Images captured in this stage should follow two requirements: a) One single image should cover at least one completed object (e.g., a completed column); and b) Images should be taken from different views and try to contain enough information for one target object. Furthermore, a series of survey and interview with O&M personnel who is in charge of data repositories are suggest to perform to collect data on current situations and problems of as-is building conditions.

Stage 2: Data pre-processing step.

Based on the summary of image processing methods and image-based reconstruction approaches in Chapter 2, various image processing methods could be chosen in this stage. Pieces of building information (including surface information, geometric representation, extracted information, and features information) are extracted from images. In this framework, Hough transform is applied to detect line elements and confirm building information.

All these extracted information is saved in an information library (Fig. 3). This library provides building information and image data sources of target objects for whole reconstruction process. In the context of this information library, the geometry of a target region, the image intensities of a target region, the properties of a target region etc. are considered as measured information that is provided to aid the recognition of objects.

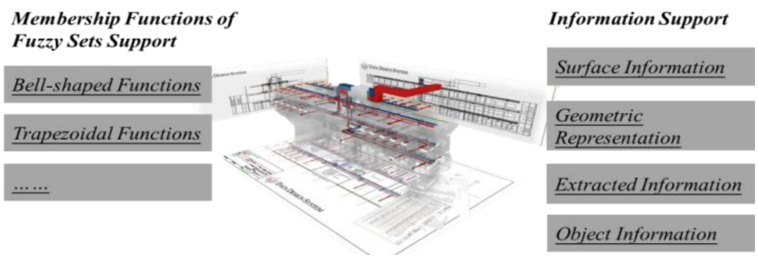

Figure 3 Modules for creating the information library

<u>Stage 3</u>: Object recognition step.

This stage uses intelligent reasoning algorithms to support object recognition and information matching. In particular, in order to take into account possibilities of information shortage and inaccuracy in the data in the forms of images and documents, fuzzy logic systems that can reason with imprecise information can be considered to adopt. From the preliminary studies on different intelligent algorithms, the hybrid neuro-fuzzy system is one of the most suitable algorithms for this framework. Fuzzy logic methods can make decisions even with incomplete or uncertain information. However, individual fuzzy logic methods cannot automatically acquire the rules used to make those decisions and has its own limitations. While, neural network is quite useful to deal with cases that relationships between inputs and outputs are complex. The hybrid neuro-fuzzy system combines fuzzy algorithms with neural network systems in order to overcome the limitations of each individual technique. Interpretability and accuracy, which are main strengths of the hybrid neuro-fuzzy method, are the key criteria of choosing algorithms (Chen and Pham, 2000; Robert 2001; Sumer and Turker, 2013).

According to building information stored in the information library, object recognition and information matching is implemented adapting the hybrid neuro-fuzzy algorithm (referring to Fig. 4). The recognized object with its related building information and the existing documents of the target building is developed to be the reference for constructing the BIM object. Then, descriptors are created to assist deciding and recognizing properties of the target object. The descriptors have two main functions: a) to bridge between the recognized object and the information library; b) to guide and connect the primarily recognized object to a matching BIM element type to construct a BIM object. Standard data models such as Industry Foundation Classes (IFC) can be embedded in the information library or BIM libraries in BIM authoring tools such as Families in Revit can be linked to the information library as the reference BIM element types in this process.

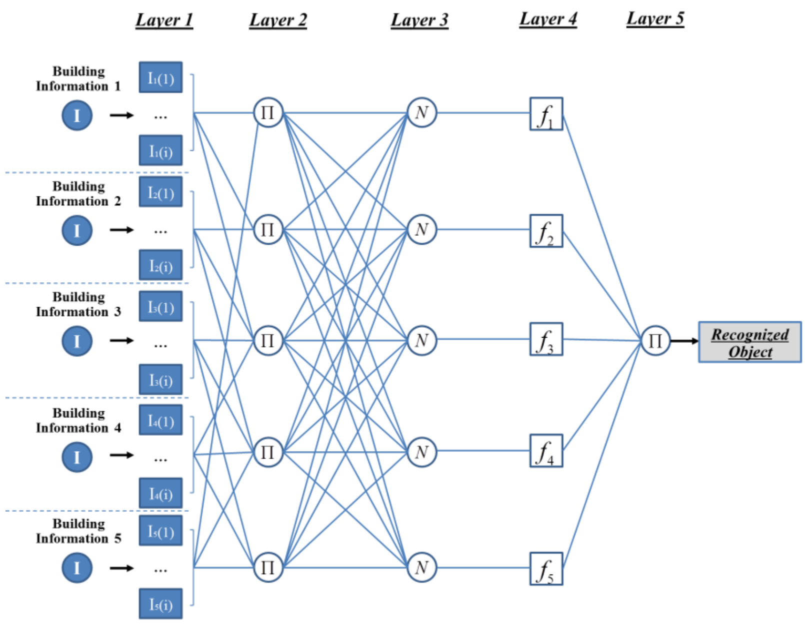

Figure 4 Process of object recognition by adapting the hybrid neuro-fuzzy algorithm

Stage 4: The as-is BIM model constructing step.

Referring to the images and existing CAD documents in the 3rd step, the exact BIM elements have been constructed. Since the as-is BIM model is not just a simple 3D geometry model, each independent BIM objects require specific classification, location information and relationships with other elements. This step organizes the individual BIM elements identified, and generates a complete an as-is BIM model, which based on LOD requirements and its functions. A further model check and validation is also necessary in the last step based on all the collected information.

4. Research Progress

Our research progress is at the 2nd stage now, which is the information extraction from collected images. Different image processing methods has been analysed in Matlab (shown in Fig. 5 left side). The Harris method and SIFT method are used to detect keypoints, and the Robert and fuzzy logic methods are used to detect edges. Image in the middle of Fig. 5 is collected by our research team using a digital camera (camera type: Nikon D7100) and it is a column of the parking place in one of the campus office buildings. We developed an application to detect necessary information (e.g., color and angle) from the collected images, as shown in the middle part of Fig. 5. It follows the route 2.1 in Fig. 2. Meanwhile, we also developed another application based on the Petzold Media3D library provided by Wu, X.S. (2009) to process CAD drawings in dwg and pdf file formats in order to confirm the location of each component (See the right part of Fig. 5). It is the route 2.2 in Fig. 2.

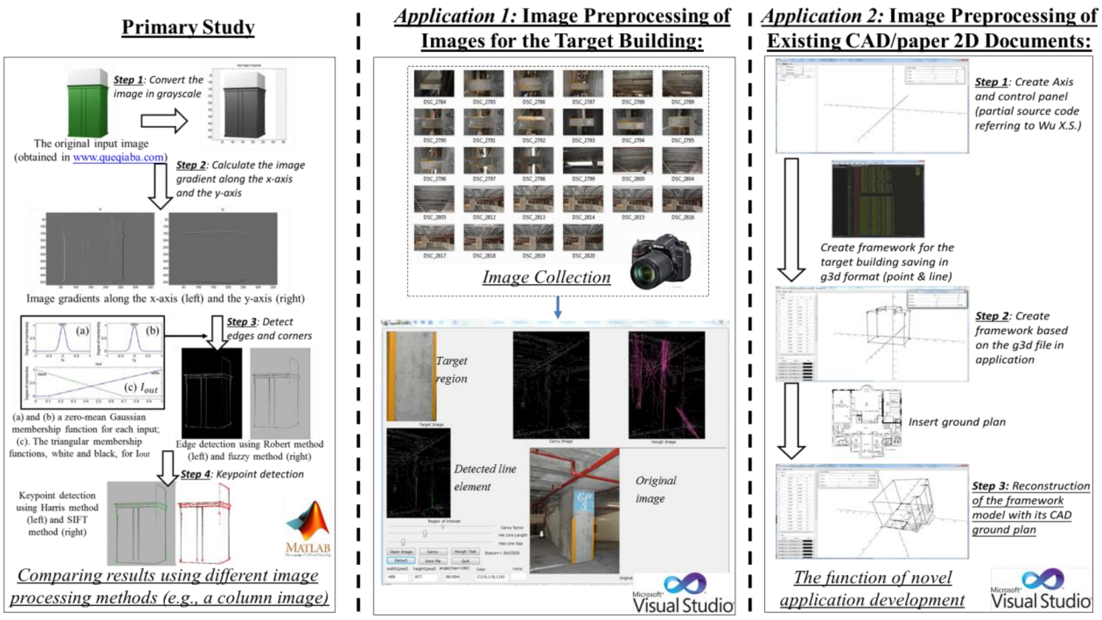

Figure 5 Research progress of information extraction

5. Discussions

The construction of an as-is BIM model focuses on surveying the geometry and surface of an existing building, improving this collected information into a primary semantically rich model and finally achieving a building information representation referring to the level of details (LoD). However, there exist various uncertainties and difficulties in this construction process, including:

- From modelling aspect: How to classify different building components in a high-efficient way? It is not easy to distinguish the target column from surrounding environments because of extra noises such as their decoration.
- From information aspect: How to collect the building information in a low cost way? It is usually expensive and requires skilled workers in building survey stage.

The framework presented in this paper aims at developing an automatic image-based approach to address these problems. It is expected that this framework of constructing as-is BIM has following merits:

- Images collected by using common digital cameras can be used as an input data, which is at relative low cost.
- The mechanism used and developed to implement the framework such as the hybrid neuro-fuzzy algorithm is suitable to recognize building elements from images, especially taken from environments that require uncertain or approximate reasoning. For instance, it is expected that the mechanism can extract building information by processing images taken from different angles of the target building, which could reduce the possibilities of producing recognition errors.

6. Conclusions

In order to achieve sustainable development throughout the lifecycle of a building, especially the O&M phases, it is urgent to adopt BIM in facilitate operations and maintenance of an existing building. Consequently, it is important and necessary to construct as-is BIM models for existing buildings. However, current methods and technologies of creating as-is BIM models mainly depend on extensive human effort and time. Although data may be collected automatically from diverse sources and methods (e.g., camera), managing useful data, recognizing building objects and conducting building logical relationships are all performed in manual or semi-automatic ways. In order to systematically automate the process of constructing as-is BIM models from images, CAD drawings and possibly other data sources, this paper gave a brief summary of fundamental image processing method, image-based building reconstruction approaches and existing systems to construct as-is BIM models. Then, we built a framework of an integrated approach to achieve the goal. The framework consists of four steps: data capturing and building surveying, data pre-processing, object recognition and BIM model creation. This framework aims to provide a foundation and guide to develop a system to construct as-is BIM with rich building information, without the requirements of extra high cost and skilled workers. We are at the 2^{nd} stage of implementing the framework. We have developed modules to process column images and tested the modules using images taken from typical office buildings. Our future works include implementing the 3rd and 4th stages and test the framework with different sets of office buildings in Hong Kong.

Diffusing BIM – knowledge integration mechanisms and their effects

John Lindgren and Kristian Widén

School of Business, Engineering and Science, Halmstad University, Sweden
Email: john.lindgren@hh.se

Abstract

Building Information Modelling (BIM) has for a number of years been seen as a systemic inter-organizational innovation that will have great impact on the efficiency of the construction process as a whole. In this study both successful and unsuccessful attempts to diffuse a BIM-service in the construction sector by a building material manufacturer has been studied through multiple data collection methods. Of special interest has been in what ways knowledge has been integrated, i.e. what mechanisms has been used in the case, since it is a key area for diffusion, and this is described and discussed. Furthermore, the contextual characteristics of the construction sector have been highlighted as influential on diffusion, especially when it comes to areas such as learning, flow of knowledge and feedback loops. Therefore, the context of the different cases and in what ways this affects the knowledge integration process is also described and discussed.

Keywords: Building Information Modelling, Diffusion, Systemic Innovations, Knowledge Integration Mechanisms

1. Introduction

BIM, Building Information Modelling or Management has in many ways been seen as an innovation that will result in drastic changes for the construction process at large (see for instance (Succar, 2009, Elmualim and Gilder, 2013). Eastman et al. (2011) describes BIM as the change of moving from paper-based modes of communication, i e using drawings on paper through the construction process to a process based on using electronic information and tools. This change has taken place and been developed through the use of ICT with web-pages, 3D CAD tools etc, avoiding some of the problems connected to the traditional process. The implementation and diffusion of BIM also generates a number of difficulties (see for instance (Succar et al., 2012). This can in many ways, among others, be related to the general problems related to diffusion of inter-organizational innovations, also called systemic innovations. Systemic innovations are holistic and relational to their nature (Colvin et al., 2014), require change of processes in a coordinated fashion by multiple firms (Taylor and Levitt, 2005, Taylor and Levitt, 2007) and cover multiple relationships (Powell, 1998). Systemic innovations can be a number of innovations that together perform new functions, the relationship in-between the innovations are explicit, but most often there will be effects on other components or systems as well (Slaughter, 1998). Manufacturers and suppliers who are unaware of the changes required to implement their innovations, either in the links to other components, processes, or systems or in the product itself are likely to meet resistance in the spread of their products (Slaughter, 2000).

ICT development focus has for long, maybe too long, been on technical issues, and not on the diffusion perspective (Peansupap and Walker, 2006). BIM is in its nature inter-organizational with its focus on managing information throughout the construction process, and for construction, diffusing inter-organizational innovations poses many challenges. The characteristics of construction can be described by: the physical nature of the products and the structure of sector, the production of single/unique structures, the different types of clients (Briscoe, 1988), the importance of maintenance (Manser, 1994), iterant process, and the derived nature of demand (Bon, 1998). Production in construction is project-based and encompasses a large number of actors from different industrial sectors (Salter and Torbett, 2003).

Attempts at systemic innovation may prove to be problematic. Taylor (2006) has highlighted a number of constructs that influence diffusion of systemic innovations. These relate to the magnitude of the innovation and the level of change it has on affected parties and processes; the amount of "new" involved actors in each project, I e the *organizational variety*; the *interdependence between tasks*; *the boundary strength* or rigidity between trades; *span*, I e the number of affected professions and finally the alignment of the innovation with the work allocation in the network. A key issue related to these constructs it that they influence the ability for inter-organizational knowledge to flow. Knowledge creation and exchange is a key issue in the innovation process and its inherent diffusion (OECD, 2005). According to Rundquist et al. (2013) an ineffective flow of knowledge and limited knowledge integration constitutes a barrier for innovation. An additional complicating factor for construction is that in construction projects different types of professionals come together to work for a limited time; architects, engineers, project managers, craftsmen etc. These professionals have different knowledge types that needs to be managed through knowledge integration, i e combining new and previous knowledge (Wijnhoven, 1999, Rundquist, 2012). Knowledge integration can be done through different types of mechanisms that depend on different amounts of social interaction (Van De Ven et al., 1976, Grant, 1996). Due to these factors, choosing the most efficient mechanisms is central and following this, *the aim of this research is to investigate what mechanisms has been used in one case when diffusing BIM, since it is a key area for diffusion, and this is described and discussed. Furthermore, the context of different cases is described and its effects on knowledge integration are discussed.*

2. Knowledge integration, mechanisms and knowledge types

Knowledge is at the centre of the research presented in this paper. Knowledge is viewed as information, technology, skills and know-how in line with Grant (1996), with a view on objective information as codified knowledge (Grant, 1996, Nonaka and Takeuchi, 1995). Codified knowledge is of special importance since it facilitates the transfer of knowledge (Prencipe and Tell, 2001). Finding ways to use codified knowledge for knowledge management is of interest for construction (Styhre and Gluch, 2010), although construction research has shown that construction is hesitant to codify and formalise knowledge (Styhre, 2008, Bresnen et al., 2005, Scarbrough et al., 2004). Senaratne and Sexton (2008) mean that codification could increase, but an important factor is that it should be done in balance with soft personalization strategies.

In research on knowledge management in general many different sub-concepts are used, and construction is no exception. Examples in construction are knowledge management (Robinson et al., 2004), sharing of knowledge (Styhre and Gluch, 2010, Styhre, 2008), and knowledge sharing and creation (Bresnen et al., 2005). In a comprehensive review on the concept of knowledge integration and concepts with similarities, Rundquist (2009) treats the concepts knowledge transfer, knowledge sharing and knowledge application. A main point in the review is that knowledge integration is a broader concept that covers the other concepts. This view is shared in this research. In Rundquist (2012), knowledge integration is defined as a process of combining new and previous knowledge. A similar definition is made by Wijnhoven (1999) saying that knowledge integration refers to the process of acquiring, sharing, and making use of knowledge by incorporating new knowledge into an existing knowledge base. Although both authors mean the same thing, Wijnhoven (1999) is a bit more explicit and forms a basis for this paper.

An objective for mechanisms is to integrate knowledge as efficiently as possible and mechanisms can be classified on a scale ranging from low interaction to high interaction. According to Johnson (1992) technological change requires more social interaction like dialogue and conversation and the more advanced innovations, scientifically and technically, the more complicated communication processes are required. Another implicating factor according to Van De Ven et al. (1976) is insecurity, i e difficulty and variability in the conducted work also affects what mechanism to use. This means that it is not just the level per se that sets affects what mechanism to use, but also how the work is perceived is influential. More insecurity requires more personal mechanisms. Another useful way of classifying mechanisms used in construction research relates to explicit and tacit knowledge, and a division of mechanisms into tools and techniques. Tools rely on the use of IT to share explicit knowledge. Techniques use a more human-centered approach to transferring mainly tacit knowledge (Carrillo et al., 2006, Carrillo, 2004).

Our main focus here is to have the level of interaction as a point of departure. We use four types of mechanisms defined by Grant (1996) as a point of departure that range from a scale of low to high interaction for integration of specialized knowledge; *Rules and directives* are un-personal methods such as plans, schedules, forecasts, rules, policies and communication systems; *Sequencing* treats organizing production activities in sequence to enable every specialist to do what he or she should; *Routines* are performed automatically and can be conducted simultaneously when the person conducting them are well acquainted with them and sees them as natural activities that we do without giving them much thought. The first three can be seen as a way of avoiding costs for learning and communication, and the last mechanism *Group problem solving and decision making* is as the title shows a mechanism with communication and interaction. The need for this mechanism increases with the growing complexity and insecurity in the activities that should be conducted as stated by Grant (1996).

3. Method

The study presented in this research focuses on a reinforcement company, the construction process of which the company is a part and their development and diffusion of BIM and BIM-related solutions and services. The study consists of data collection in two steps. The first step of data collection was initially used to map the situation of the case company through a broad approach focusing on the development of the company and its context. The initial mapping focused on content (what has changed), process (how has it changed), why has it changed (context) which is an important interplay for understanding changes (see (Pettigrew and Whipp, 1991, Carlsson, 2000). The collection of data in step one lasted for about 6 months and comprised analysis of company documents, websites and 24 semi-structured interviews with company (internal) and external respondents. The semi-structured interviews provides a structure for meaningful interviews and discussions but also flexibility (Andersen, 1994, Merriam, 1994). The questions addressed the business situation of the company, including its development, objectives and challenges. The character and context of the construction industry, its development and IT related issues were also included. Development aspects are considered interesting from a diffusion point of view since they provide a picture of what ideas, solutions, products and services that are spread (diffused) and not. The interviews lasted from 30 minutes to two hours and were recorded. After the interview the whole interview was listened through and transcribed, although not transcribed in detail. Time-positions was written into the transcripts if sections of the recording were needed to listen to again. The material was summarized in a company report and the extraction has been done from this material and the transcripts, with a focus on the purpose of this paper and *on BIM as the change of moving from paper-based modes of communication, i e using drawings on paper through the construction process to a process based on using electronic information and tools.* The broad collection of data provided useful understanding for the findings.

Based on the extraction of data a new round of semi-structured interviews was conducted with four company internal actors; the technical manager, a sales representative working towards manufacturers of prefabricated elements, one team leader for the BIM/reinforcement engineers and one BIM/reinforcement engineer. These actors are working with diffusion related activities and the new round enabled an update of the situation from the first round and questions regarding the purpose for this paper were raised. The highlighted definition above was communicated in the interviews and the additional questions this time regarded what type of BIM and BIM-related solutions and services that has been diffused, to whom, why and under what circumstances. The compilation of data from the first round served as a support material and also enabled specific questions about the development of specific services. Company information about BIM and BIM-related solutions and services was also overviewed. The time between the two steps of empirical collection was afterwards considered useful to provide a view on development is progressing. The material was overviewed, summarized and analyzed a number of times to find themes and categories that relate to the aim of the study. This was made from the collected data and the section *Results from and analysis of the study* show the final compilation of the collected data.

4. Results from and analysis of the study

The case study company is an international supplier of reinforcement and the Swedish affiliation was studied. The Swedish company has undergone development in line with the steel industry at large, with closures, mergers driven by a focus on economies of scale. This has led to increased competitive pressure not least from low cost countries. Due to the development and the extremely low development potential in the material, reinforcement, the company has put a lot of efforts on developing complementary services to strengthen the company´s competitive position. Among these are electronic solutions or solutions that build on such. The company has worked extensively with 3D-models with included information and 3D-visualisation, and on managing transfer of information back and forth from different systems. By using company solutions, information can be transferred between different systems and much can be automatized, for instance electronically generated specifications lists, visual planning is enabled, print-outs from different views and documentation. The company has introduced a new software in which reinforcement is specified, and it has many add-ons enabling electronic transfer between systems especially with the CAD-software. The company had a predecessor to the software, with many users, and by stopping development of that software, they have forced users in to the new version. Other services that are offered are assembly instructions and a service called color sorting and labelling. In short, this means that reinforcement comes sorted and labelled for simplified assembly. A result from the company´s development is that the company has created their own niche as a technically competent player with BIM and BIM-related solutions and services affecting customer’s processes and approaches.

4.1 Contextual factors

In the study it is evident that contextual factors affect the diffusion of BIM and knowledge integration regarding BIM, which are presented in the following text.

Project stress, short term view and a divided chain: Especially in the first round of interviews these factors were highlighted as affecting development and diffusion in general and thereby also BIM. An effect was that actors use the same solutions as they always, for instance to reduce insecurity and risks. By moving from one project to another without a proper evaluation and use of experiences this is not facilitating diffusion of new solutions such as BIM. It was also stated that different parts of the chain work with their part, not interacting to the extent needed. Subcontractors, like the case company often also come in to late in the RFP-process eliminating room for improvement and possibilities to come up with ideas and solutions.

Organizational width and rules: For starters a key issue is that individuals and organizations need to see benefits with the solutions and has an overall process focus. In the study, actors in the end of the construction chain were not considered pushing development further to a large extent. One approach enabling diffusion was that some of the large construction companies have decided that some projects should be defined as BIM-projects. This is of course of help for diffusion. A highlighted barrier from the external interviews was also that development needs investment that in turn needs to be paid, which many small companies cannot afford, so much development must be driven by larger companies. Since BIM spans many actors, organizations and process steps, the interviewed actors in step 2 all mean that organizations covering many steps of the chain and has a broad business are highlighted as most interesting and also pushes development forward in a way that others don´t. It might be that by working with BIM, activities in the chain are moved and changed. There might be additional work for one part of the chain but with a benefit for the overall efficiency. A possible explanation highlighted is that they can see overall effects of different solutions. However, it was also highlighted that rules within the companies, which can be rigid in larger companies, could be a barrier for implementation, for instance when installing software, support is needed from an IT-department and there could be rules regarding what software that is allowed to install. One mentioned example was also that turnkey contractors have other possibilities to develop solutions from their overall perspective and can be of great importance to move development forward. Another slight point was also that commitment and push from top management was evident in the more forward moving companies.

Personal characteristics and maturity: One of the key factors highlighted in the study is the impact of “IT-ability” among people as having impact on the diffusion of BIM. Many interviewees also thought that construction was lagging behind other sectors when it comes to IT-usage, especially interviewees with experience from other sectors. One of the external companies also had a clear strategy of NOT being first in the development of ICT-solutions, but instead implement solutions when it is clearly shown that they work. Overall, an opinion was that IT-usage should improve as the amount of young people increase, since they are more used to using ICT in their everyday life. Cloud-services, integrated services etc are common in much social media that is used today. The main factor that was enabling diffusion was however individual characteristics. People who are interested and use ICT-solutions enable diffusion.

Implementation in real projects and ease to implement: One of the key factors for diffusion highlighted in the study is to present and implement solutions in real projects. When showing the solutions in real projects, the company has been able to immediately use the solutions and show their immediate effects. An additional key factor has of course also been that the solutions are easily learnt and installed and not requiring too much additional efforts. The coloring services for instance, although not having to do with BIM, was considered easy to implement since they required no additional efforts by customers. 3D-visualisation as a discussion tool was for instance greatly helped by an adobe-application in which 3D-objects could be opened and rotated. It was also highlighted in both rounds that knowledge about IT-implementation has improvement potential especially in the area of supporting IT-implementation on construction sites, for instance to accomplish knowledge integration between developers and operative personnel in understanding user needs and prerequisites and to educate on site. An additional point is also that when the company got external users in their solutions, this created an interest for the company´s other solutions.

Product type, usage and usefulness: Since a main part in BIM is 3D-models, this was specifically discussed and also led to highlighting other factors. It was concluded that 3D-models/visualization was useful to create an understanding for what a product or a specific object looked like, how it could be handled, and what problems that could arise and enabled lowered differences in interpreting the product. However, it was also stated as important not to overuse visualization since they were most useful for complicated objects. In the first round it was also evident that interviewees thought that it was most important to focus on increasing effectivity in relation to everyday operations, instead of having focus on the more visionary aspects. As the technical manager pointed out, everything is expected to go fast and simple.

4.2 Used mechanisms and their effects

The contextual factors presented above are important for the used mechanisms to become successful. Diffusion has been done through various types of mechanisms from high to low interaction with varying results, such as information letters, brochures, sales presentations, information meetings etc. The diffusion of the services has internally been considered moving slow, but the interest for the solutions has increased heavily. The company has presented solutions at various occasions. At first they were seeking interest from customers to implement the solutions and a first modest strategy was to get the solutions "out". The company used a push-strategy to diffuse solutions in real projects with consideration to the contextual factors presented (these factors are also results from failed implementation and diffusion). Implementing the solutions in real projects has been done in several ways. Often instructions were sent out to users and a YouTube video has been used as a mechanism. Often when the company has made follow-up calls they have referred to this video and new users have been able to start up solutions by themselves. Company representatives have also been present at start-up meetings having time to help new users set up their solutions and they have also provided support for users not just by answering questions, but also by being pro-active and making follow-up to get users going. An indication from this is that more interaction intensive mechanisms are needed at the start but then users work easily by themselves.

One of the regional managers also stated the importance of being present and show oneself physically at the customers. This is important to create trust and it is also a method that sells products and services. This emphasizes construction as sector with face to face contact. An example of the usefulness of being present and work in projects is that the company has visited projects with 3D-visualizations of real project objects. By using this push strategy, people in projects have been "forced" to work with the solution and many have also stated that they really could see the benefits. Anyhow, according to the interviewees, customers seldom ask for 3D-models and the demand was actually stated as larger in-house for complicated, welded products, since the 3D-models visualized what the product should look like (which of course is a benefit to the customer since the product is correct). An important part as stated by the technical manager is also that when the company launches new solutions, it is important for them to educate and create a demand for the services. This in itself highlights the need for more interaction intensive mechanisms for starters and when the need is established, other mechanisms can be used.

4.3 Summary of findings

To summarize the findings, the study shows that there are a number of contextual factors that influence diffusion and the knowledge integration that is needed for diffusion of BIM and BIM-related services and solutions. Thereby, the contextual factors also influence the choice of knowledge integration mechanisms. More interaction mechanisms are most likely needed in the start of a diffusion process and a key determinant for the choice of mechanism(s) is the knowledge base of the target groups.

5. Discussion

Speaking in metaphors, BIM can in many ways be the same as changing language. This metaphor is useful to create an understanding of the sometimes large magnitude of change that the entrance of electronic solutions constitutes in relation the former use of printed drawings and other paper-based methods in construction. Once again it is evident that contextual factors of construction complicate diffusion. *Project stress, short term view and a divided chain* has been mentioned many times in previous research and it also becomes evident that these characteristics form a basis for the rest of the contextual factors. A point regarding the divided chain is that by not interacting, knowledge integration is efficient from the perspective of “getting the job done”, but from a knowledge development perspective, potential new knowledge useful for the overall effectiveness of the chain is not being integrated.

For a systemic innovation like BIM, inter-organizational to its nature, diffusion in construction seems to require customers with control over several parts of the construction process. Both in the study and in previous research it has been shown that controlling the chain is of importance, either as having the overarching responsibility/control as emphasized here and in for instance Hjort et al. (2014) or by ownership of resources as highlighted in Taylor (2006). In the same manor, this can also be a barrier for diffusion, with actors having the prerequisites not using their power to implement and diffuse new ideas. What´s interesting in the case however, is that a supplier has the possibility to push the development forward and affect customers also, by taking contextual characteristics into account. As noted in the case and by Taylor (2006), it can also be concluded that the amount of adaptation in the process affects diffusion.

Another interesting point in the study is that construction seems to have a lot of potential in developing their change management and implementation skills. A key topic seems to be to make different actors of the construction chain meet and thereby start a knowledge integration process. In a way, knowledge integration is efficiently managed by different parts working autonomously together as emphasized by Grant (1996), but for knowledge development to take place it is necessary to incorporate new knowledge into an existing knowledge base as in the definition used in this paper (see Wijnhoven (1999)). As the in the study, the reinforcement company seems to take their point of departure in the existing knowledge base and also seems to have accepted the current situation in construction. Based on the point that young people have another knowledge base regarding IT, a potential impact is that it will probably be easier to diffuse BIM in the coming years as there is a shift in active generations. The overall maturity regarding IT should therefore increase, but this is of course also dependent on solutions becoming easier to install and implement. Older generations have most likely created a habit on how to do things based on their experience and for many this is based in an era where IT was not as visible as today. Besides taking the knowledge base into account, the study also points out the need to solve day-to-day issues besides working with visionary aspects to start the change process. By solving “easy” problems, I e bringing forth solutions that solve problems with little or less effort from customers AND showing the potential in real projects, an interest for other solutions from the company becomes interesting.

When it comes to mechanisms the study does not contradict the preferred use of soft-personal modes in construction and the combination of mechanisms as pointed out by Senaratne and Sexton (2008) . If the existing knowledge base does not deviate to a significant amount in relation to the “new”, personal contact can be said to be preferred in the start-up phase, but then codified knowledge can be used, i e more interaction intensive mechanisms starts the diffusion process and then codified knowledge can be used. Traditional codified knowledge, i e information in written form, seems also in this study less useful in construction. On the bright side, it is indicated that a useful mechanism to diffuse codified knowledge are instruction films (You Tube). This points out the potential of spreading codified knowledge using other mediums and in line with Senaratne and Sexton (2008) it advocates codification in balance with soft personalization strategies, i e highlights *combination of mechanisms* as useful. However, it´s not just about choosing the right mechanism to diffuse a solution, it´s also about having future adopters in focus, support these in the best way and make set-ups and systems simple.

It can be noted by the results that more interaction is needed along the chain with a more overarching focus which points in the same direction as pointed out by Taylor (2006) when comparing BIM implementation in Finland and USA. One of the key differences was differences in viewing the chain, where the US had a short term view and divided approach in the construction chain and Finland had a more long term view and a more cooperative process. A conclusion was that BIM-implementation was more favorable in Finland due to a more integrative view on the construction process.

6. Conclusions

Based on previous research and this study it is evident that *Project stress, short term view and a divided chain* affects knowledge integration necessary to diffuse BIM and BIM-related solutions. Due to this and the decentralized work-model, it is of significance to create a demand from the projects to use BIM and BIM-related solutions. A push-strategy has been found useful as a phase one strategy in order to create a need for BIM-solutions and thereby creating a pull from the “market” i e the projects. The influence from the organizational width and its set up of rules is also visible, where an organization with a wider set-up of businesses along the construction chain is more likely to successfully implement BIM due to the ability to control the construction process. At the same time, the study shows that a small niche player also can affect the diffusion of BIM and its customers if contextual characteristics are taken into consideration in the implementation process.

With BIM and the transformation into an electronically managed information chain, different parts connect and become more dependent on each other. In addition, a key issue in the study is that adaptation to the existing knowledge base is of central importance for the diffusion of BIM. It is indicated that a major problem for the diffusion of BIM is the level of general knowledge about IT in construction. A higher knowledge level regarding IT seems to facilitate diffusion and as younger generations come into the sector the diffusion of BIM will most likely become smoother and faster. This is further enabled by the development of solutions that are easy to implement and understand. The study validates soft-personal modes as most useful and frequent in construction and validates the combination of different mechanisms as useful for efficient diffusion. The study furthermore indicates that new media can improve the diffusion of codified knowledge. Finally, an important aspect highlighted for the mechanisms is the necessity to introduce solutions in real projects, to show immediate advantages and discuss actual problems.

A final indication from the study is the need to develop change management and implementation knowledge to implement and diffuse solutions. Of interest for further studies is therefore to study approaches of implementation and change management in construction and evaluate what approaches that are specifically useful in construction research. Since the study also highlights that general knowledge regarding IT is of help for the diffusion of BIM, it can be of interest to study how knowledge in general or from other sectors can be used and implemented in the construction context and also what barriers that exist. In addition, the study has treated the aim in general and to validate the results further it could be interesting to go in more in detail in specific cases to get a picture of the diffusion from both inside the company and outside the company.

Level 3 BIM for Standardised Design Delivery, Refinement and Optimisation: Is it a real option in the UK?

Esra Kurul, Akponanabofa Oti and Franco Cheung

School of the Built Environment, Oxford Brookes University, UK
Email: ekurul@brookes.ac.uk

Abstract

Building Information Modelling has been hailed as a panacea which will overcome the endemic fragmentation and collaboration issues in the UK Construction Industry. The Government's target to make BIM mandatory for all public projects from April 2016, and its roadmap to Level 3 BIM are extensively discussed in the literature. It is now clear that a number of large main contracting companies such as the Kier Group, Laing O'Rourke have been positioning themselves as the market leaders in the delivery of projects using BIM. Despite such developments, the Government's push and the general desire within the industry to make collaboration happen through BIM, industrial experience points to a number of important issues which can only be resolved by changing the way building projects are developed and delivered; and the way facilities are managed. Such changes would help close the performance gap by establishing feedback loops between operations, construction and design stages.

This paper reports on the findings of an Innovate UK-funded research project which aims to bring about these fundamental changes in the delivery, refinement and optimisation of standardised school designs. It sets the background by describing the context of this joint-venture between a major UK contractor and a local authority owned specialist offering national procurement frameworks. The multi-method approach to collecting, analysing and making sense of the case study data is explained. The key issues in achieving and using Level 3 BIM, e.g. competing processes and systems within the main contracting company, different levels and extents of use amongst the design and delivery teams, are then identified through one aspect of this case study. This discussion paves the way to establishing when, where, why and how Level 3 BIM should be utilised. The paper thus makes a novel contribution to the existing literature on BIM as it illustrates that BIM is not necessarily one size that fits all in terms of collaboration.

Keywords: BIM, collaboration, UK, standardised designs

1. Introduction

There have been a plethora of initiatives and discussions on the implementation of BIM in the construction industries across the World. It is commonly argued that the implementation of BIM will help these industries overcome their endemic reluctance to collaborate and thus achieve cost and time savings, and improved quality. Industry professionals, especially those who have had the experiential knowledge of using both CAD and contemporary BIM tools, will support claims that the capabilities and advantages inherent in the latter surpass the former. An extensive literature directed towards demonstrating the benefits of BIM either through implementation studies (Becerik-Gerber and Rice, 2010; Migilinskas et al., 2013; Li et al., 2014; Poirier et al., 2015) or some form of conceptual extension of the scope of different applications (Schlueter and Thesseling, 2009; Azhar et al., 2011; Wong and Kuan, 2014; Oti and Tizani, 2015) support these views. This literature, however, tends to rely on the perceptions of professionals of the benefits of BIM or of academics who theorise on how these benefits can be quantified in projects. Moreover, the uptake and diffusion of BIM appears to be slow across the industry. Certain studies (Azhar, 2011) have attempted to capture the reasons for such slow rate of diffusion. Despite this, there are indications that an evaluation of the current levels of BIM adoption is necessary to judge whether the desired Level 3 maturity is realistic in the UK. This paper aims to make a contribution to providing this evaluation through a ‘real-life’ BIM implementation case study.

It is divided into six sections. The second section outlines the case study context. The third section describes the methodological approach. An extensive literature review is then provided as evidence that there is a gap in the literature in terms of ‘real-life’ cases evaluating the implementation of BIM. A description of the design review meeting and the following user feedback session, which is the core of this paper, follows. The findings and observations are also discussed. Conclusions are drawn at the end of the paper.

2. The case study context

The case study that is presented in this paper is undertaken as part of an Innovate UK-funded research project, which is led by a British Main Contractor. The case study context is the delivery of standardised school designs as turnkey projects using a national framework agreement, which is set up by a public sector owned built environment specialist. Standardisation is particularly important for this project delivery approach as there is a clear advantage of using knowledge from one phase of the project life cycle to improve other phases. For instance, feedback from the operations phase can help to achieve continuous improvement of the standardised designs for potential future clients.

The Main Contractor aims to develop and adopt strategies to utilise the power of BIM in delivering, refining and optimising the standardised design as a ‘product’. This research project focusses on the integration of project data from construction and operation stages in a BIM environment and the capacity of BIM to facilitate collaboration between the main contractor, their consultants and supply partners. These ideas are tested as part of the continuous improvement of the 'product'. Thus, the opportunity for evaluating a 'real-life' BIM implementation approach to delivering projects is exploited. This paper reports on one aspect of this approach, namely the use of BIM in a collaborative design review meeting.

One of the first key deliverables of this research project was to develop a 3D federated model using the architectural, structural and M&E design models, locating the BIM implementation at the border between Level 1 and Level 2 BIM (Figure 2). The aim of the research project was to move this initiative to Level 3 by establishing and utilising feedback loops from the construction and operations phases of the building life-cycle. One aspect of this plan was to use Autodesk BIM 360 Field and Glue during the construction phase in order to integrate the project reporting and snagging information into the integrated model. This plan could not be implemented for three main reasons. First, 360 Glue/Field applications did not support the Main Contractor's sophisticated H&S reporting processes in an automated manner. Secondly, there were issues around the amount of training that the site team would require and whether it could be accommodated within a very tight and relatively short construction phase. Third, the Main Contractor started to use Priority 1 to report snagging while these discussions were taking place. Priority 1 was considered to be a more suitable platform than integrating the H&S reporting process into 360 Field/Glue. Fourth, the standardised design and its delivery processes were set up such that the lessons-learnt from the construction stage and the associated requests for design change would be incorporated into the Design Review meetings. Hence, it was decided that the regular Design Review Meetings between the Main Contactor, their design consultants and Supply Chain Partners would be a more appropriate venue to evaluate whether the integrated BIM could enhance collaboration between partners.

3. The methodological approach

The rationale behind using a Design Review meeting as a 'test-bed' for the use of BIM for collaboration purposes was explained in the previous section. This section describes only the methodological approach utilised in order to collect data during a design review meeting, and to subsequently analyse it. The overall methodological approach adapted in the whole project is out of the scope of this paper.

A predominantly qualitative approach was the obvious choice for understanding how the use of BIM influenced collaboration within the design team, which included supply-chain partners, and the closure of the feedback loop from operations and construction stages to the design stage. The lack of existing research in this area and the opportunity to study the complex phenomena of collaboration and learning from experience in its natural setting were the fundamental reasons behind this choice. The design review meeting was set up to provide an occasion for real-time observations, and to gather feedback from the participants at the end of the meeting.

The key supply chain partners were challenged to come up with ideas on reducing the time it takes to weather-tighten the envelope. The architectural design consultants, roof contractors, aluminium systems and insulation suppliers, and representatives from the main contracting company, were represented at the meeting. Researchers attended the meeting as impartial observers to collect data on the means and tools of collaboration that participants used. They also ran a real-time survey and a short focus group.

The participants were asked to complete a short questionnaire at the beginning of the meeting. This questionnaire was designed to collect demographic data and to establish each individual's BIM readiness. This data was used in making sense of individual's responses to the survey and the focus group discussions. The survey and the focus group aimed at gathering feedback from the participants on whether and how they thought the use of BIM influenced real-time collaboration. TurningPoint was used to collect survey data anonymously, and to display the results in real-time. As a result, it was possible to identify the key issues, i.e. those on which there was consensus or divergence of opinion, and thus to concentrate the focus group discussion on these issues. The focus group discussion was recorded. Key findings emerged from the content analysis of the focus group discussion.

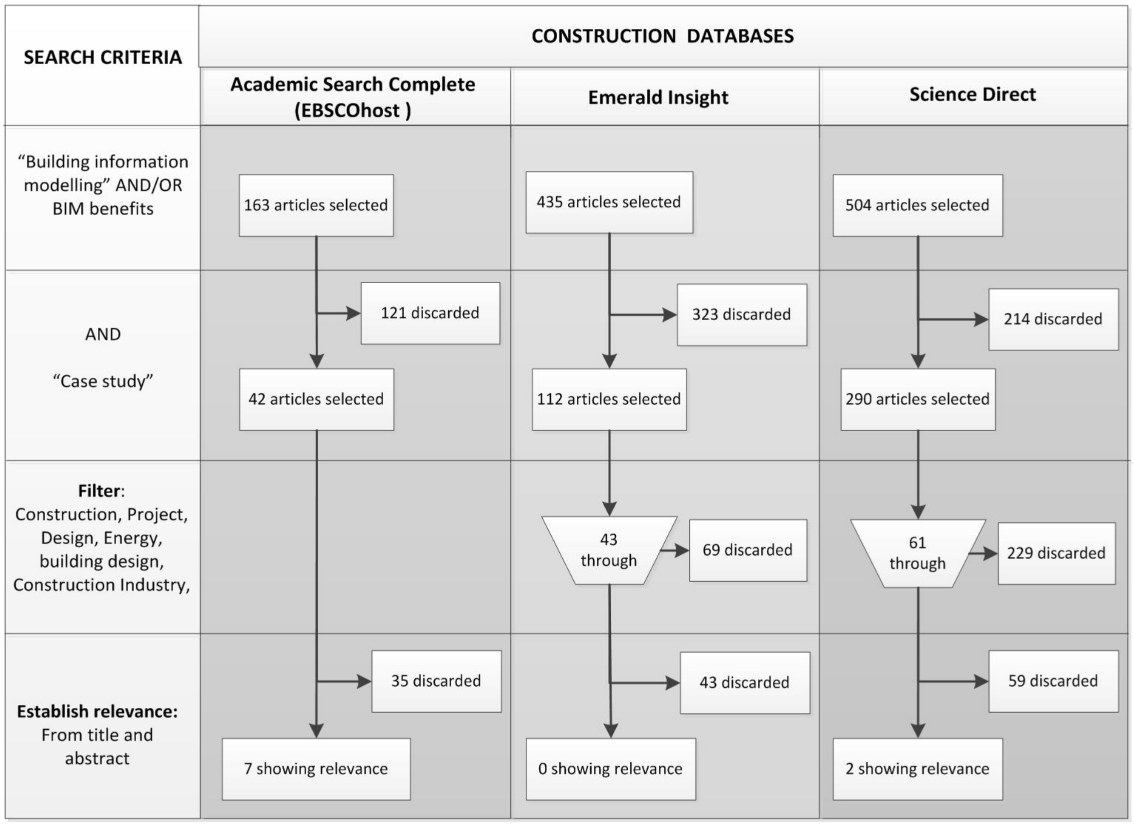

Figure 1: Literature search description

This case study was complemented with an extensive literature review. The aim was to establish the extent of existing knowledge on 'real-life' BIM implementation case studies with respect to Level 3 maturity. Three scholarly, cross and multidisciplinary databases, i.e. Academic Search Complete, Emerald Insight and Science Direct were chosen as they provide access to foremost literature in the construction sector. Database searches were undertaken using these keywords: building information modelling, BIM, case study and benefits. The results were further refined by filtering them using construction, project, design, energy, and building design as additional keywords in Emerald Insight and Science Direct. The EBSCOhost interface did not allow for the search results to be refined in the same way. The results are displayed in Figure 1. This filtering yielded 41 – 61 search returns in respective databases. The authors then scanned through the titles and abstracts to establish actual relevance. The systematic review therefore focused on the nine papers summarised in Table 2, and critically reviewed in the next section.

4. Literature review

It is important to start with an overview of the current state of BIM adoption in the industry. There is evidence in the literature that the uptake of BIM has been increasing across the globe. In the UK, the National BIM Survey Report focusing on SMEs indicated that the number using BIM rose from 13% in 2010 to 54% in 2013 (NBS, 2014). Similarly, Kiviniemi et al (2008) suggests that the ratio of BIM tools to Computer-Aided Design (CAD) use among companies in Denmark, Norway, Sweden and Finland is likely to increase from about 1:3 in favour of BIM. On a global scale, there have been positive indicators from the annual studies consistently conducted since 2007 by McGraw Hill Construction to gauge impacts and uptake of BIM in leading construction markets such as Canada, France, Germany, UK, US, Brazil, Japan, Korea, Australia and New Zealand (McGraw-Hill Construction, 2014). In most of these 10 countries there have been active efforts by both the private and public sectors to encourage the uptake of BIM. For example the UK government mandated government projects to be executed using Level 2 BIM maturity (Figure 2) from April 2016 (BIM-IWG, 2011). This has resulted in chains of events ultimately geared towards catching up with the BIM implementation boom. A number of higher education institutions have introduced BIM applications into their curriculum. There are a significant number of BIM- related research projects funded by the UK Government. Also, public institutions such as the BRE run short training courses (BRE, 2015). Workshops are also being held to promote the adoption of BIM by firms in the AEC industry. Despite all these efforts, it appears the industry is still struggling to get a full grasp of Level 2 BIM maturity.

Professionals are expected to be working in their separate software environments and models with the opportunity for federation at Level 2 Maturity (Figure 2). It is argued that such federation should aid with reducing the number of clashes between the designs provided by different disciplines. When this maturity level has been fully attained, it is expected that the industry will naturally attain the Level 3 BIM maturity.

Despite these aspirations, at the moment, it is difficult to establish from the literature whether and how well Level 2 BIM maturity has been achieved by the industry. The relevant literature (Table 1) that discussed BIM implementation tend to demonstrate the benefits of BIM through surveys of practitioners' perceptions built around notions already established via BIM promotion campaigns (Gilkinson et al., 2015; Poirier et al., 2015). Others theorize how the benefits of BIM can be quantified on projects (Barlish and Sullivan, 2012; Lu et al., 2012; Pilehchian et al., 2015). However, robust empirical evidence detailing actual experiences of BIM adoption during the various phases of the project lifecycle is lacking in the literature.

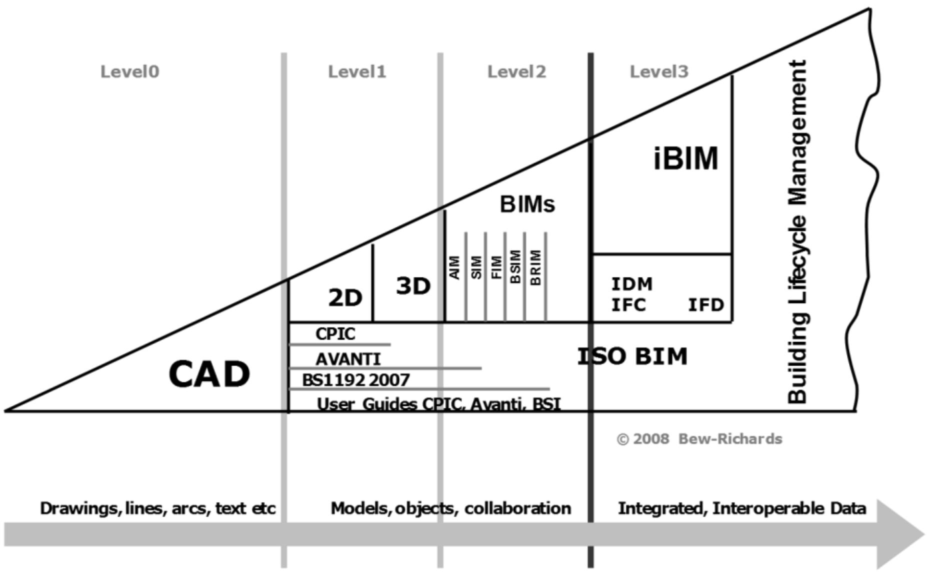

Figure 2: BIM maturity levels (BIM-IWG, 2011)

The lack of evidence becomes even starker when the literature search results of 1102 articles are filtered and the results discarded for their relevance, i.e. reporting on 'real-life' benefits of BIM implementation. Only 9 of the original 1102 report on BIM benefits are based on practical experience of implementing BIM in any stage of the project life-cycle (Table 1).

Gilkinson et al (2015) discussed the benefit realisation based on six case studies that relied on popular BIM tools such as Revit, ArchiCAD and Allplan 3D. The aspects of BIM application in these projects include the architectural design of Knowsley Schools, Royal Opera House mechanical, electrical and plumbing design services, the structural steelwork of North Lakes Police Station and the Heathrow Airport Energy Centre, the services engineering of 1 Bligh Street, Sydney – a 28 storey building, structural design of four high-rise blocks of Wood Lane studios of an academic institution and the planning/scheduling of the extension of Queensland State Archives. The authors suggest that the tide may be turning in favour of BIM following the changes in the UK government policy as contractors and their sub-contractors will have to be BIM-ready to be able to secure centrally- funded contracts from April 2016. They also advocate the move from a building information model to a building knowledge model in order to exploit all the benefits of a digital model. Migilinskas et al, (2013) featured four cases executed in Lithuania using various BIM-enabled tools (STAAD.Pro, Bentley Structural, Bentley Triforma, Allplan, Tekla Structures and CADVENT). The aspects of BIM application included planning and design, construction scheduling and facility management in these projects. Azhar (2011) provides an earlier, similar study covering planning and design, construction scheduling/documentation and sustainability analysis of three case studies in Georgia, USA, and identifies associated trends and benefits in the AEC industry.

In a rather more detailed study of ICT innovation on a large hospital project in the UK, Davies and Harty (2013) discussed the implementation of 'Site BIM' system for site workers to use mobile tablet computers to access design information, capture work quality and progress data on site. The tablet computers access coordinated 3D models developed in BIM-enabled tools hosted on site office servers equipped with document management system connected to a site database where progress reports, compliance targets, defects information and 3D viewer are logged and hosted. The authors argued that the use of Site BIM can be justified due to the large scale nature/complexity of the hospital project and the construction management procurement approach which required speed. Adjudged to be successful, the project was rolled out by a small team of construction project staff and enrolled IT personnel. Although details of BIM tools utilized were not clearly mentioned in the study, the accomplished tasks respectively appear similar to the functions of common data environment and field applications such as Buzzaw/BIMSight and Autodesk BIM 360 Field that were used in our case study.

Table 1: Literature on BIM implementation benefits

Research source	**Origin of study**	**Area/ life cycle phase**	**Main features**
(Gilkinson et al., 2015)	UK	Design, Construction	• Reports on a number of case study research projects • Identities benefits, challenges and opportunities
(Poirier et al., 2015)	Canada	Renovation construction works	• Based on action research • Measurement of labour productivity
(Lu et al., 2012)	China	Construction	• Based on the use of learning curves • Proposed measuring benefits of BIM as a learning tool on site
(Pilehchian et al., 2015)	Canada	Design	• Use of graphs and dependency matrix • Monitoring of design changes and their dependencies
(Barlish and Sullivan, 2012)	USA	Design, Construction and Post-completion	• Combined literature and case studies • Developing a holistic methodology to quantify BIM benefits
(Eadie et al., 2013)	UK	All stages of construction project	• Use of web-based questionnaire survey to gather information • Designed to gauge perception and experiences of participants in BIM implementation • BIM is more extensively used during the early stages of the project-life cycle
(Bynum et al., 2013)	USA	All stages of construction	• A survey-based analysis of BIM implementation • Application of inferential statistics on findings to establish relationship between BIM and project delivery
(Lindblad and Vass, 2015)	Sweden	Organisational management	• A literature and a case-based study to identify associated organisational change effected in steering documents and work process due to BIM implementation
(Davies and Harty, 2013)	UK	Construction	• Case study of 'Site BIM' system implementation • The use of mobile tablets to access design information, capture quality and progress of work on site

This literature review illustrates that various scales and approaches of BIM case studies exist. However, studies which evaluate the use of BIM as a collaborative tool which facilitate the closure of the feedback loops from operations and construction stages to the design stage are missing. Moreover, more focused and detailed recounting of actual experiences is required to encourage cascading of candid practical accounts through the industry. In this light, this study presents lessons from the actual experiences of BIM application in a standardized turnkey project delivery. In this project, BIM is utilized as a learning platform to close up the operation/ construction-design feedback loop.

5. The Design Review Meeting as a Collaborative Learning Platform

As stated above, the Design Review Meeting focused on reducing the time it takes to weather-tight the building. The participants are involved in the design and delivery of the product both at the strategic, developmental and operational levels. Each attendee has at least ten years' experience in the industry. The delegates from the architectural consultants and the Contractor's BIM Manager were the only delegates who have high levels of experience in using BIM environments. The majority of the participants (6 out of 9) had low levels of BIM-readiness.

The Product Director of the Main Contracting (MC) company chaired the meeting following an agenda that would enable collaborative envisioning of possible solutions. The BIM Manager of the MC walked the attendees through the 4D model and showed the construction simulation based on the 4D programme of one of the schools. Attendees also viewed a time-lapse video of the construction phase of the same project. An informal discussion which broadly followed the pre-determined agenda ensued. The attendees were willing to share their ideas and make suggestions for reducing the time to weather-tightness. In this context, high levels of collaboration were observed among the participants who were all driven by a desire to continuously refine the standardised design and bring about efficiencies in its delivery.

Despite all the intention of facilitating collaboration through the use of BIM, the use of the construction simulation and the federated model during the meeting was very limited. Throughout the meeting there was a preference towards using 2D information that had been drawn out of the 3D model. In one case, a 2D print out was quicker to make available than its digital version as a pdf file. The time-lapse video was preferred to the construction simulation when visualisation was required. It could have been argued that the time-lapse video is more effective in facilitating real-time collaboration than the construction simulation in this particular context. However, relying on time-lapse videos mean that the variations to the schemes are not considered as part of the Design Review Meetings. Although this business model centres around a standardised design, about 70% of the schemes are adapted for various reasons.

Perhaps the low levels of BIM exposure among the event delegates is the reason behind the little use of the construction simulation and the preference towards the time-lapse video. It also points toward the need for training but more importantly a focus on changing the way people conduct their day-to-day business, if the capacity of BIM to facilitate real-time collaboration is to be exploited. This change can only happen if every company involved in refining and delivering these standardised designs are convinced that only BIM can deliver the business performance that will render each company a leader in their field. As identified by Lindblad and Vass (2015), even a large public client, which intiated BIM implementation in their own organisation, is not yet certain how BIM should and would influence the organisation. Hence, there is a need for robust methods for evaluating the impact of BIM on a business' processes and performance.

The results of the anonymous feedback survey show that the majority of the attendees (7 out of 8) either agree or strongly agree that 4D visualisation made it *easier* for the delegates to share their ideas at the meeting, and *encouraged* them to share their ideas with others. One of the Product Managers working for the Main Contractor explains why:

> *"..when you bring the model up there, you are not trying to interpret it from a 2D drawing. It is the same as standing on site and looking at the detail and saying 'can we do that better'…"*

The Sales Director of the Aluminium Systems supplier corroborates as follows:

> *"I get involved in structural design very early on. Sometimes the Structural Engineer overdoes it for me. When I look at the 3D model, I can ask why certain elements are there. Then, they tell me that they are to receive my products and I tell them that I do not need it. Hence, early on in the process you can make an input. Very useful. Very easy to understand where the other person is coming from."*

This finding contradicts with the findings of Eadie et al. (2013) which identified that "the visualisation benefits were thought to be not as significant as the increased collaboration, reduction of waste and accuracy".

Same positive responses were also achieved when the attendees were asked whether they were more willing to contribute ideas. The reasons behind this score also centre around the ease of understanding each other as a result of having access to the model. The BIM Director of the architectural consultants explains:

> *"You do not have to explain something to somebody. You can point to it. You can say: 'look this is what I am talking about'. It is much easier than saying: 'you know the little bit under the eaves …'*

It should also be noted that some of the delegates believe that collaboration is in the nature of this group mainly because they are involved in refining a standardised design. In this context, members of this group are already willing to share their ideas with each other. The 4D model makes the communication during the meeting more effective rather than facilitating collaboration in the first place.

Only 3 out of the 8 respondents agree or strongly agree that it was easier to coordinate the meeting as a result of 4D visualisation. Nearly all respondents are neutral that 4D visualisation helped identifying programme reduction opportunities or potential conflicts in the design solutions proposed. As such, the 4D visualisation facilitated a more effective *sharing* of ideas but it has not helped with *evaluating* the implications, e.g. cost and time, of incorporating these ideas into the design. Delegates reported that this evaluation was better done in a more traditional way outside the meeting. The Product Director of the Main Contractor explains:

> *"If you are considering what could have been done differently, by its nature you have not modelled it yet. If you have not modelled it yet, you cannot look at it in the software. It is more appropriate if people went away from this meeting, modelled stuff up, and we centred our discussions at the next meeting around [the model]. I think that would be really, really, really useful. We are a couple of steps before that point. I would say BIM helped us get our bearings today but we could have had a photo instead….*
>
> *BIM is one of the tools at your disposal. Some tools are better at a certain juncture than others…. [BIM] is never going to be as intuitive as taking a felt-tip pen out and sketching it, unless your model is super-duper."*

The BIM Director of the architectural consultants further elaborates:

> *"You use a meeting like this to inform you when you go away. Everybody still works in their individual silos on their models which are then federated, obviously, and then clash detected. You could not necessarily work on your model because it is on your server and the engineer's model is on his server till you get to a Level 3 environment where they are all stored in the same place. Even then, you are trying to access them remotely. So, the reality of it is, you all get together, you go through it in Navisworks, or whatever you are using. You make your notes, you mark the model up. You post that model. You go back to the office. You download it and you look at it. You make the changes. [A model] is incredibly useful in the right place."*

This discussion illustrates that, at least in this context, a clash-detected digital model is produced following the traditional approach to integrating the architectural, structural and mechanical designs. It is clear that these professionals do not consider real-time collaboration to be an option even when Level 3 BIM is achieved. Also, the standardisation of the design and its delivery mainly using a framework contract seem to be more influential in facilitating collaboration than the BIM, which is considered to be valuable for visualisation purposes. This suggests that this team is a relatively long way away from Level 3 BIM and Gilkinson et al.'s (2015) suggestion to move to "building *knowledge* models". More importantly, the professionals imply that one needs to establishing when, where, why and how Level 3 BIM should be utilised, rather than considering it to be a panacea for the industry's collaboration issues.

6. Conclusions

The literature review demonstrated that there is a gap in the literature in terms of 'real-life' BIM implementation. One of the small number of case studies that can be found in the literature identified the scale, nature/complexity of the project and the procurement approach to be the key justifications for using BIM. User feedback from this case study points to similar situation. The standardisation of the design and the use of a framework contract for delivery play a more important role in collaboration than the use of BIM.

In this particular context, 4D visualisation is considered to help with sharing ideas and coming up with solutions to existing problems. This team considers that real-time collaboration facilitated by BIM is neither desirable nor possible in their context. Hence, BIM and other means of nD visualisation remain to be enablers rather than collaboration tools in themselves, placing this case study closer to Level 2 than Level in terms of BIM implementation.

Although it is impossible to draw general conclusions from a single case study of a very specific approach to design and delivery, the literature review and the case study point to the importance of companies considering the implications of their BIM implementation strategy in different contexts. As such, project characteristics such as type, scale, complexity, procurement method, and the ease with which internal processes such as H&S reporting can be incorporated in the use of field applications such as 360 Field and Glue, should be taken into account. The development of a BIM implementation matrix with these characteristics would enable companies determine which projects are most likely to benefit from BIM implementation. The authors have identified the development of this matrix as a future research opportunity.

Building Information Modeling; a New Business Trend in the Construction Industry of Iran

Navid Sanei Sistani[1] and Alireza Rezaei[2]

[1]Helsinki Metropolia University, Finland

Email: navid.saneisistani@metropolia.fi

Abstract

Building Information Modeling (BIM) is a 3D design tool that has been widely used in the developed countries and has become a profitable business. However, this procedure in developing countries is proceeding slowly. This research looks at BIM, as a new business tool, and uses SWOT (Strengths, Weaknesses, Opportunities, and Threats) analysis (a business method) to specify and analyze internal and external motivating factors in the construction sector of Iran. It also investigates industry readiness for implementing BIM in Iran. A questionnaire survey was conducted among a number of different parties within the construction industry. The outcomes of the survey were used to determine most important strengths, weaknesses, opportunities, and threats of BIM application in the construction industry and SWOT analysis was performed. Based on the survey results, internal environment properties (strengths and weaknesses) and external environment possibilities (opportunities and threats) were prioritized from respondents' point of view. Regarding to survey results, structured interviews were conducted to formulate strategies for decision makers to introduce the new trends and encourage the construction companies to apply BIM in their projects.

Keywords: Building Information Modeling, BIM, SWOT Analysis, Construction Industry, Developing Countries

1. Introduction

"Construction is a large industry of small firms" (Fellows et al., 2002) that is divided into two major sectors: general building construction which includes residential, commercial, institutional and industrial buildings and engineering construction which includes highway construction and heavy construction (Bennett, 2003).The construction industry is a massive business with more than $3.9 trillion annual turnover and employs around 7 million directly and hundreds of thousands indirectly in the world (Jackson, 2010) it is estimated that in 2008 the construction industry in the US spent around $1.288 trillion (National Institute of Building Sciences, 2007) with 2.53 million construction companies in 2007 (Levy, 2009). Buildings consume 40% of the world's raw materials and 40% of the world's energy (65% of U.S. electrical consumption is used in building); therefore, the construction industry plays an important role in energy consumption, economics and politics. Producing 40% of carbon and 20% of waste materials of the world, the construction industry has considerable impact on the environment. Taking into account these characteristics and over $600 billion estimated waste in the U.S. construction industry (National Institute of Building Sciences, 2007), it is essential to manage the construction projects.

Project management is applicable in the construction industry regardless of the size and complexity of the projects (Chartered Institute of Building, 2002). Construction management is defined by Patrick (2003) as "planning, scheduling, evaluation, and controlling of construction tasks or activities to accomplish specific objectives by effectively allocating and utilizing appropriate labor, material, and time resources in a manner that minimizes costs and maximizes customer/owner satisfaction." Bigger and more complex construction projects require larger and more professional workforce. The project team must be effectively coordinated to achieve project goals. For this reason, 3-D modeling has been developed by technological advances to build a virtual model by computer much prior to construction phase (Levy, 2006). Manufacturing industries like the automotive industries have integrated design, production and operation phases by virtual design of their complex products. This technological approach has been applied to construction industry in the shape of BIM (Jones, 2008).

Smith (2007) defined BIM as "a digital representation of the physical and functional characteristics of a facility and shared knowledge resource for information about a facility, forming a reliable basis for decisions during its life-cycle, from the earliest conception to demolition." It is essential to consider that BIM should not be the goal, it is just a tool to help project members to achieve their goals (Kymmell, 2008). BIM caused a revolution in the construction industry (Jones, 2008). As stated by Weygant (2011) "Just as CAD (computer-aided design) improved upon hand drafting, BIM is improving upon CAD. The difference is that BIM involves so many more project participants than just the architect." However, this improvement has not been started yet or it is still in its infancy in some developing countries. In order to implement BIM in developing countries, it is essential to analyze the construction industry to discover its potential.

SWOT analysis in the construction industry has been performed in some studies. For example, Lu carried out SWOT analysis for the strategic planning in China, Ling et al. (2009) used it for A/E/C firms in Vietnam and Lee et al. (2011) conducted SWOT analysis for the strategic management in Korea. However, such an analysis has not been performed on BIM application in the construction industry in Iran. This study aims to bridge this gap.

2. Methods

A SWOT analysis has been conducted in this research. The SWOT analysis consists of three stages: identifying SWOT factors to know the internal specifications and the external elements which might affect the industry; designing SWOT matrix to provide a summary of the industry's current situation and make strategic decisions to maximize utilization of resources strengths; gain profit from opportunities, minimize significant weaknesses and eliminate threats (Thompson et al., 2009).

A questionnaire consisting of three sections was designed. The first section was general information about respondents for further use in categorizing the data. In the second section, the level of knowledge about drawing and design tools and software was evaluated by close ended questions. This section provides awareness around the current situation of the construction industry's parties and their skills. The third section contained questions about SWOT factors in the construction industry for BIM implementation. The characteristics of BIM and the construction industry in Iran had been studied through a comprehensive literature review and accordingly several alternatives for each factor were considered to determine their importance by 7 points Likert scale (zero representing not important and 6 representing most important). Based on the results of previous researches (Sanei Sistani, 2015, Sanei Sistani and Rezaei, 2012), practitioners in the consultants, design, and construction companies with basic knowledge about BIM were selected as respondents. Out of the 100 questionnaires that were distributed, 60 were responded.

Since the level of knowledge about BIM among Iranian construction industry practitioners is not so high and strategic management need broad knowledge about BIM, afterward, face to face structured interviews with 10 professors of civil engineering and architecture were performed. Based on the interviews, a SWOT matrix with two rows (opportunities and threats) and two columns (strengths and weaknesses) was prepared as a solution to overcome threats and weaknesses by managing strengths and opportunities. Considering four quarters of SWOT matrix, S-O (Strengths-Opportunities), S-T (Strengths-Threats), W-O (Weaknesses-Opportunities) and W-T (Weaknesses-Threats), analysis was carried out and strategies for decision makers were formulated.

3. Results and Discussion

SWOT factors for the construction industry in Iran were considered as a result of a detailed literature review and were validated by questionnaire survey as listed in Figure 1.

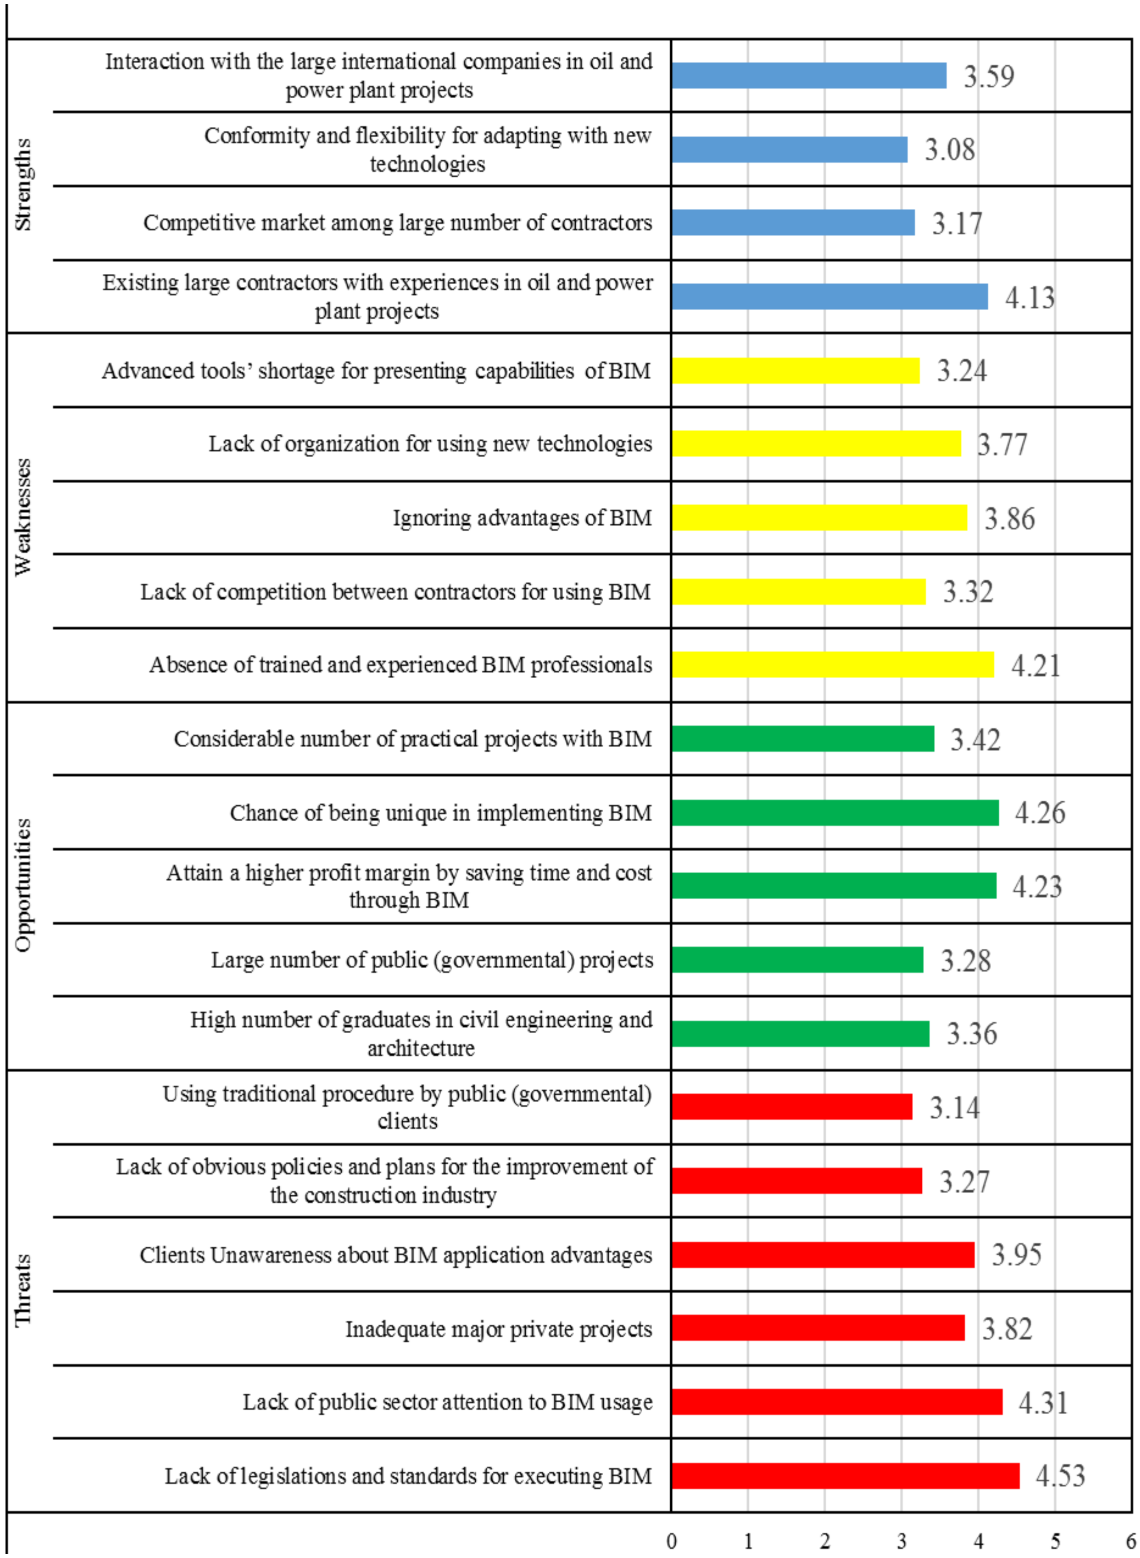

Figure 1. Weighted means of SWOT factors based on questionnaire survey

3.1 Strengths

Existing large contractors with experiences in oil and power plant projects Like other Middle Eastern countries, oil plays a vital role in Iranian economy. Due to cheap and easy access to oil, the number of power plants have been increased considerably. Petroleum and its related industries (oil platforms, oil refineries, pipelines, power plants, etc.) form some of the biggest construction projects which require serious attention in this section. Due to these needs, the domestic contractors tried to improve their capacities in executing huge projects (Faani et al., 2014b). Working on these types of industrial construction projects provides valuable experiences for the construction industry.

Competitive market among large number of contractors By increasing the number of graduates in civil engineering and architecture, the construction firms grow simultaneously. The more firms in the construction market, the more competition for winning the bids. The firms try to adapt themselves to new technologies; otherwise they will lose competitions (Sheikh Khoshkar et al., 2014).

Conformity and flexibility for adapting with new technologies The entry of a new generation of civil engineers and architects to Iran's construction industry, the industry's adaptability to new methods and technologies have been improved (Vatankhan et al., 2013). Their potential to advance makes the construction industry flexible towards the technological changes and alterations.

Interaction with the large international companies in oil and power plant projects As stated earlier, the petroleum related construction industry is one of most active fields in Iran. Working in this field requires cooperation with huge international oil companies at the highest level. This close relationship between the Iranian and the international companies has many advantages for the construction industry of Iran. For example, becoming familiar with the latest methods and tools, gaining valuable experience, getting involved in the international markets, etc (Faani et al., 2014b).

3.2 Weaknesses

Absence of trained and experienced BIM professionals Some of the Iranian universities do not even offer design and drawing as core courses in civil engineering and architecture disciplines. These courses include hand drawings or at the best cases 2D CAD drawings. In this situation, the graduate of such universities normally lack 3D modeling experience (Akbari and Safari, 2014). The few that have this skill, have learned it through self-study which in most cases is time consuming and not done in a correct way. It is obvious that without proper training, sufficient experiences would not be gained (Gu and London, 2010).

Lack of competition between contractors for using BIM The most important factor that could encourage an industry to use new tools is competition. Contractors were not motivated to use new tools unless there was a demand for using those tools; in other words, there was no demand for such tools (Vatankhan et al., 2013). The supply and demand is a cycle and it is an ancient question that "which one is the start point of this cycle?"

Ignoring advantages of BIM Since the students have not had the opportunity to learn the latest design and drawing techniques and tools other than 2-D, the awareness about BIM and its advantages is very low. Adopting BIM in the construction industry demands serious attention in education and training at the first level (Asgari and Gerami, 2014). The construction management is moving from CAD to BIM, but in Iran moving from hand drawing to CAD has not been completely achieved yet.

Lack of organization for using new technologies The Iranian construction firms work with traditional design tools. BIM is a revolution in the construction industry, not only in drawing and design but also in tendering, construction, and mainly operation and maintenance (facility management). This alteration must be done by a well-organized policy (Faani et al., 2014a). Unfortunately, this organization does not exist in the construction industry of Iran.

Advanced tools' shortage for presenting capabilities of BIM BIM is a high performance technological tool and requires to be appropriately presented to its users. BIM's primary requirements including hardware, software and equipment like 3D projection and laser cameras have an important role in introducing BIM potentials (Qing et al., 2011). Obviously, in order to replace the traditional tools with the new technologies, BIM can be used as a new tool. However, BIM has its technological requirement (Akbari and Safari, 2014).

3.3 Opportunities

High number of graduates in civil engineering and architecture The annual rate of bachelor degree graduates in Iran ranges between 280 and 300 thousand yearly (Ameri, 2011). There is a high competition between graduates to be employed in the construction companies. The demand for engineers and architects with BIM knowledge encourage the graduates to learn these skills (Ahn et al., 2015).

Large number of public (governmental) projects The government is the biggest client in Iran's construction industry. Although, this limits competition among clients, but competent organizations in this sector can be effective in persuading contractors to use BIM in different phases of the projects (Tafakor and ShaterZadeh Yazdi, 2014).

Attain a higher profit margin by saving time and cost through BIM The main advantages of BIM are time and cost reduction. BIM helps to prevent the clashes during the construction phase by creating a visual model of the project at the design stage (Ahn et al., 2015). These digital 3D models are also very useful for better understanding of project specifications, from conception to commissioning. In traditional methods, the coordination between different parties in a project mainly started at the construction phase, but by using BIM, the collaboration can be started at an early phase which helps to reduce re-works and this can lead to considerable saving in cost and time (Ebrahimi and Mahmoodabadi, 2013).

Chance of being unique in implementing BIM BIM is a very new technological tool that is still in its infancy in many countries. The novelty of BIM offers an opportunity to be one of the first enterprises that implement it (Sheikh Khoshkar et al., 2014). Although there are difficulties in using a new tool for the firt time, valuable experiences can be gained and the benefits of being a pioneer in an industry will create great opportunities for any company.

Considerable number of practicable projects with BIM BIM application might not seem to be economic for a company (according to high initial investment to start using BIM). Considering the government's construction development budget of $34 billion 2011(Council of Ministers, 2011), it is clear that BIM application in noticeable number of projects could cover its initial costs in a short period of time (Mirjalili et al., 2014).

3.4 Threats

Lack of legislations and standards for executing BIM Standardization could be the first step for using BIM. The term of 'Building Information Modeling' must be clearly defined and its usage domain must be specified (Qing et al., 2011). The designers, owners and contractor must be aware of their responsibilities and duties for using BIM in projects. Whereas construction industry is very debatable, legislation is essential for preventing and solving disputes. BIM legislation and standardization must be assigned to an independent organization body and if such an organization does not exist, it can be set up (Shakeri et al., 2014).

Lack of public sector attention to BIM usage While public (governmental) sector does not attend to new technologies like BIM, construction industry faces this threat. Lack of organization in the Iranian government regarding BIM utilization has caused delays and an increase in projects cost (Faani et al., 2014a).

Inadequate major private projects Private clients try to gain more benefits by reducing time and cost. BIM could be a very effective tool in this regard, but unfortunately due to inadequate large private projects, there is a lack of encouragement and competition in the construction industry of Iran (Tafakor and ShaterZadeh Yazdi, 2014).

Clients Unawareness about BIM application advantages The clients are not aware of BIM and its advantages in reducing time and cost. Research works in construction management are not adequate and not successful in improving the clients' knowledge about new methods in managing construction projects (Faani et al., 2014a). Without awareness about BIM and its usage, the construction industry has been slow in accepting this tool (Abubakar et al., 2014).

Lack of obvious policies and plans for the improvement of the construction industry Despite the recent activities to integrate construction related ministries and spending more than 5 percent of the government's budget for construction development, there are not clear plans to improve and update construction methods yet. Transition of the construction industry from traditional to modern methods requires effective planning and defining policies in macro scale (Asgari and Gerami, 2014).

Using traditional procedure by public (governmental) clients The traditional structures of the construction industry in Iran have caused the clients to think it is risky to use BIM without the required experiences (Shakeri et al., 2014). It is impossible to use highly technical tools in the traditional systems. To improve the efficiency of the construction industry by using BIM, the construction projects procedures must be changed.

3.5 SWOT matrix

SOWT (or TOWS) matrix (Table 1.) shows how to use environmental and internal specific positive factors in the construction industry against negative external and internal factors to gain more benefit from the strength and opportunities and to overcome the weaknesses and threats.

S-O strategies are strategies for using strengths to take advantage of opportunities by pursuing them rapidly. These are future growth strategies. W-O strategies specify how to overcome the weaknesses that prevent the industry from taking advantages of these opportunities and are known as internal fixes strategies. S-T strategies determine how to use the strengths to reduce the likelihood and impacts of threats as external fixes strategies. W-T strategies are Survival strategies to overcome the weaknesses that will make threats a reality must be placed in W-T strategies quarter of SWOT matrix.

4. Conclusion

A serious trilateral synergy between educational, industrial and governmental organizations is required to persuade the construction industry to use BIM. The first step for adopting BIM in the construction industry is to show its advantages and potentials in time and cost reduction. This goal can be achieved by organizing conferences and seminars. After providing awareness and motivation about BIM and creation of demand, the educational effort must be concentrated on educating students through courses in universities; training engineers and architects through workshops and clients through conferences and seminars.

The Government must provide appropriate legislation and environment for using BIM. These legislations could be used to prevent disputes. Appropriate standards for BIM integration implementation could also be created. On the other hand, public sector must encourage contractors to use BIM. This can be achieved by making the use of BIM in large projects mandatory. Due to traditional characteristics of construction industry in Iran, institutional efforts for finding ways for transition into technological age are required. This transition needs effective policies and long-term planning in macro scale.

Table 1. SWOT/TOWS Matrix

SWOT/TOWS MATRIX	STRENGTHS	WEAKNESSES
	Existing large contractors with experience in oil and power plant projects Interaction with the large international companies in oil and power plant projects Conformity and flexibility for adapting with new technologies Competitive market among large number of contractors	Absence of trained and experienced BIM professionals Lack of competition between contractors for using BIM Ignoring advantages of BIM Lack of organization for using new technologies Advanced tools' shortage for presenting capabilities of BIM
OPPORTUNITIES	S-O STRATEGIES	W-O STRATEGIES
High number of graduates in civil engineering and architecture Large number of public (governmental) projects Attain a higher profit margin by saving time and cost through BIM application Chance of being unique in implementing BIM Considerable number of practicable projects with BIM	Provide appropriate legislation to use BIM in large public (governmental) projects Encourage contractors through contractual requirements to reduce time and cost through using BIM Training of engineers and architects to learn how to use BIM software	Educate civil engineering and architecture students to use BIM Provide awareness workshops about BIM's advantages among contractors Demand for using BIM in public projects to encourage contractors to adopt BIM
THREATS	S-T STRATEGIES	W-T STRATEGIES
Lack of legislations and standards for executing BIM Inadequate major private projects Lack of public (governmental) sector attention to BIM usage Clients unawareness about BIM application advantages Lack of obvious policies and plans for improvement of construction industry Using traditional procedure by public (governmental) clients	Partnership with private sector in public projects organizing conferences and seminars to introduce BIM Establish or assign an institute to legislate and standardize BIM	Long-term policy to improve management in construction projects Replace traditional methods with technological alternatives Interaction with international companies for implementing BIM in large projects

The construction industry has a significant role in adopting BIM. Using BIM is a sound investment that helps each company to recover its cost once and for all and enjoy its benefits in long term. This investment can be done by training engineers and designers in BIM software application in n-D modeling. Large contractors involved in national projects can drive benefit of collaboration with the international companies and use their experiences in utilizing new technologies.

Building visual models with software at first stage of projects has become popular in the construction industry. BIM as a new technological high performance tool plays a key role in the construction industry and its advantages have helped this trend to grow rapidly. In order to enjoy the benefits of BIM, close synergy between related sections is essential for the building of the necessary infrastructures.

In this research, the characteristics of the construction industry in Iran were studies through a SWOT analysis. SWOT factors were identified based on a comprehensive literature review, structured interviews and a thorough questionnaire survey. The strategies considering the external and internal factors in three main areas were suggested. These areas are education, legislation and adoption strategies which must be pursued in parallel and without priority.

Abstract

Technology for scanning is in rapid development. More advanced solutions are available for lower cost of scanning, and simple methods are available for everyone. Use of a building information model (BIM) for facility management is gaining interest, there is still a large number of existing buildings without BIM representation. As-built drawings are not updated or unreliable. However, establish a BIM for an existing property is often costly, and hard to utilize for new purposes. Time and cost effective methods for flexible use is therefore wanted. Integrated Design and Delivery Solutions is used as theoretical frame for this study. The analysis explores the steps in the process of scanning and modelling, collaboration between people in establishing the BIM, and further use for multiple purposes within facility management. An overview of technology presents in relation to process and people to give support for ordering commercial scanning and BIM services. A scan to BIM project of an old apartment building is used as case for demonstrating a framework for "Purpose BIM". This framework combines relevant technology, processes and personal resources for flexible and stepwise processes of ordering scan to BIM services. An outcome of this approach can be add-on services that can enable reuse previous work. This can result in extended use of BIM to multiple purposes in facility management.

Keywords: Purpose-BIM, process specification, product specification, scanning technology

1. Introduction

There is an increasing interest for integrating laser scanning as basis for establishing building information model (BIM). Laser scanning technology is in rapid development, likewise development of BIM software. Detailed scanning of heritage buildings is often presented as an example of the potential of scan to BIM, but most buildings are ordinary and need a more simple approach to maximize the cost/benefit relation. Even if there is a lot of available theology for scanning and modelling a BIM, the projects are often motivated by solving one single task, by use of one technological approach, often by one single provider. Development of technology contributes to reduced cost, but the traditional processes have limited flexibility and the cost must be covered by only one use-case, or benefit. Often will small changes in requirements to the BIM – result in repeating almost the entire scan to BIM process. The impact is limited establishment of BIM for existing facilities, despite the benefits for using BIM for multiple purposes within facility management.

There is an increased number of papers regarding integration of BIM, based on various methods for laser scanning in BIM related conferences. This can be illustrated by activity at following BIM related conferences; the BIM 2015 conference had one entire sessions about BIM and GIS integration (Breibba et al., 2015), and the CIB-W78 IT in construction conferences have included papers which cover solutions where BIM can be established based on laser scanning (Issa et al, 2014 and Beetz et al. 2015). This integrated focus has also reaches standardization, where ISO/ TC 211 about GIS and ISO/TC58/SC13 about BIM have joint workshop (Kim, 2012). The general focus of research is on issues related to technical interoperability, demonstration of laser scanning hardware and use of software for transforming point clouds into 3-D geometrical models and BIM.

The outcome of this concept paper is useful for building owner / facility manager (client) for design of specification or requirement for ordering scan and BIM services – especially when the purpose is not limited to only one purpose. Expected impact is increase return of investment. The outcome for service providers of scan and BIM services is in improved accuracy of deliverables in relation to client current and future needs. The proposed framework is called “Purpose BIM” and includes all elements from preparing of the project, capturing information by laser scanning, processing of information into BIM, and various ways of presenting results for different users and use cases.

2. Technology overview

2.1 Overview of methods and processes for scan to BIM solutions

The process from the decision to capture geometrical data describing the building to establish a BIM for solving one or more purposes consists of several steps. To be aware of these steps and the options within each steps can make it possible to order according to the principles of “purpose BIM”, see figure 1. This is possible even if purpose is unknown or multiple.

Representation of points, z,y,z	Creating a 3D volume model (mesh)	Establish building objects enriched with attributes and relations	Building information model of a building

Figure 1: Overview, main stages in the scan to BIM process

Awareness of these steps, and potential between the steps and within each step, is one of the main motivation for this study, and will be explored later on in this paper. Use of the "Purpose BIM" is presented as a framework for an improved ordering of services to enable flexible use and options for future use with positive cost/benefit of the BIM model.

2.2 Overview of capturing geometrical data

Today there is a large variety of instruments used to create a BIM for an existing building. In this paper, we will refer to this as Interoperable Technologies, with reference to IDDS (2013) presented later in this paper. The different technics are mainly:

- Use the original building drawings (both digital and paper based)
- Tape measure (ruler or handheld laser)
- Static point based laser measurement (e.g. "Flexijet" or total station)
- Static laser scanner (terrestrial laser scanner mounted on a tripod)
- Laser scanner and other instruments mounted on a moving platform

We focus on the laser-based methods. These approaches have developed dramatic in recent years and have changed the way we capture indoor data. The "static point based laser measurement" approach use the concept "less is more". This technique has a direct link into the modelling software, e.g. by use of Flexijet. The modelling and enrichment of the model is done on site. Which in many cases has a big advantage. On the other end of the scale, you find "laser scanner and other instruments mounted on a moving platform" which use a "more is less" approach. The goal is to measure as much as possible and also the same objects as often as possible. This method has taken technics from the robotics into use. The technique is called Simultaneous localization and mapping (SLAM). This is the key concept in autonomous robotics. The robot use SLAM to create a map of the surrounding and at the same time place itself in the map. This concept is now used by many manufactures of indoor measurement systems. These systems are special made to rapid create a building model. These techniques give new opportunities and new challenges. One problem with the more is less approach is that you also collect information that might be sensitive for the people living or working there. In such a situation, the data need to be handled with care. Different techniques have different accuracy capability and the performance improve rapidly with time. We have manly talked about laser scanners, but new software can put the traditional photogrammetry into new life. Examples of software are Autodesk Memento (https://memento.autodesk.com/about) and Agisoft photoscan (http://www.agisoft.com/).

2.3 Software for processing and enriching of scanned data

There are many different software, that can be used to perform the modelling work, adding attributes and relations to the building objects. Typically software is EdgeWise Building™ from ClearEdge3D (www.clearedge3d.com/), Pointsence for Revit from Faro (http://faro-3d-software.com/) and RECAP from Autodesk (http://www.autodesk.com/). It is also relevant to mention the DURAAK project (http://duraark.eu/).

To fulfil a real BIM the collected measurement of a building has to be enriched. This process is called Integrated Processes (see figure 2) in this paper (BIM-ing). To enrich the measurements different software solutions can be used. Some software are standalone solution, but most are plugins into typical architectural software like Revit from Autodesk, Archicad from Graphisoft and Microstation from Bentley. One important difference between the software solutions is the level of operator interactions, which is needed to create the BIM. This is often a time and cost consuming operations. Another difference is how the building objects are placed related to the point cloud. In most cases, the operator can select different settings, which will place the object based on Gaussian distribution, best fit or with different kind of assumption. Typical assumption is that two walls should meet perpendicular and that a wall should always be vertical.

3. Framework for scan to BIM

The dominating focus when exploring scan to BIM has been technology, which is presented in a systematic way. Other organisational issues are often very randomly explored and presented. It is therefore a need for a framework that include technology in a systematic way. In this respect is the Integrated Design and Delivery Solutions (IDDS, 2013) as theoretical framework. IDDS can be regarded as simplification of the socio-technical theory (Bostrom & Heinen, 1977) which is adapted to the AECOO construction industry. The IDDS framework is developed by the International Council for research and Innovation in Building and Construction (CIB) in order to optimize construction projects. IDDS is a powerful framework to explore and understand interactions between different imperatives. The three imperatives of the IDDS are illustrated in figure 2.

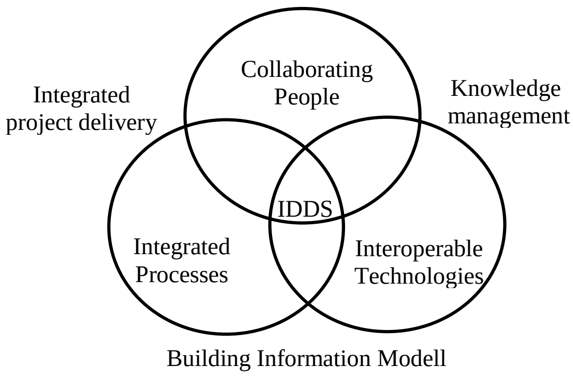

Figure 2: The three imperatives of IDDS (2013), figure simplified by the authors

In our study of the process of establishing a BIM for multiple purposes within facility management, we have used the model in figure 3 to describe the collaboration. Figure 4 illustrat the current situation in the case used in this study.

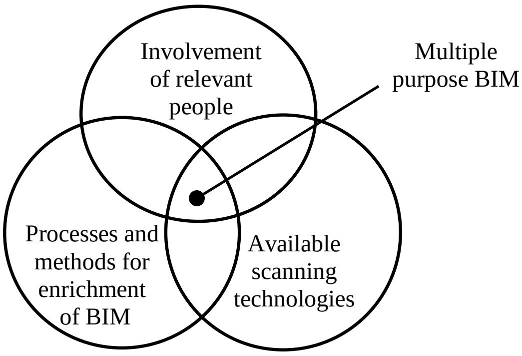

Figure 3: Identifying imperatives for multiple purpose BIM based on IDDS

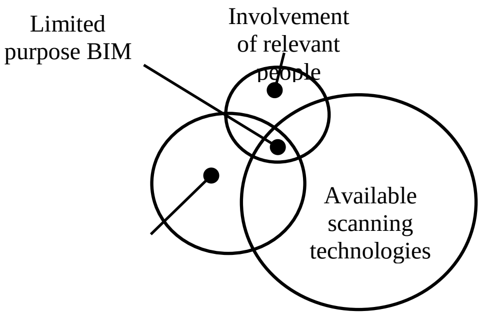

Figure 4: Example of unbalanced IDDS and limited purposes of scan to BIM

The different imperatives are in our case exemplified by the following content:

- Involvement of relevant people (Collaborating People): architects, engineers, land surveyors, BIM specialists, landlords, residents,…
- Available scanning technologies (Interoperable Technologies): drawings, tape measure, laser scanner, total station, Flexijet, rangefinder, camera,…
- Processes and methods for enrichment of BIM (Integrated Processes): Software and methods for creating BIM.

The size of each circle can be changed due to current resources, e.g. the amount of relevant and available technology or the number of collaborating people. The relative position of the circles may also change according to the interaction in between the imperatives. Examples of this are the degree of harmonization of software and hardware or the maturation of new processes in the user communities. The resulting size of the centre region can then be regarded as an indicator for the possibilities for success. Small circles with large internal distance make it difficult to succeed. An example with very good harmonization of hardware and software, but with a limited number of skilled and collaborating people is shown in figure 4. The two lower circles are highly overlapping in figure 4. The problem is that the circle representing the relevant people purpose is small. The consequence is that command area for all three circles is very limited compare to figure 2 and 3. This means that the resulting BIM has very limited purposes.

4. Framework for Purpose BIM

Our evaluation of the case study is that an ordering guide would be useful for the collaborating people. The goal of an ordering guide is to maximize the common area between collaborating people, technologies and processes. The purpose is to help the buyer to order the product, that has the potential to give the best cost benefit ratio. A spin off to this is that the provider of BIM easy can understand the customers demand and expectation. In the early days of airborne laser, the industry had a problem. The buyers of airborne laser data had a poor description of their expectations. They had very different knowledge about airborne laser data and different approaches to control the result. The consequence was that some suppliers took the benefit of this and delivered data with bad quality, knowing that the probability to be discovered was minimal. After some years, the buyers became more professional and establish detailed specification and methods to control the result. The result of the new specification was that the quality of the products became more even. Another important effect was that the different providers could compete based on the same understanding of the customers expectations.

The first step in our framework is to establish a development plan with focus on collaborating people. This will decide which persons who have interest in the project and who should have access to the result. Another aspect is who should continue to work with the BIM to ensure that it is up to date. When the BIM is up to date, it is a “Living BIM”. The second task is to get an overview of the different challenges the collaborating people have and how BIM can be used as a tool to solve their problem. Based on this the accuracy level of the data capture can be established.

Table 1: Accuracy Levels of Data Input to further proceeding BIM model

Accuracy level	**Level 1**	**Level 2**	**Level 3**
Description	Rehabilitation	Area information	Management/develop
Relative accuracy *	0.003 m	0.01 m	0.03 m
Maximum average deviation *	0.01 m	0.04 m	0.10 m
Maximum deviation between measurement and model (at 1 meter above the floor)	0.01 m	0.03 m	0.10 m
Modelling assumption	Exact modelling. The object should be placed on the average location of the point cloud	Exact modelling, but walls can be straighten up to be perpendicular to the floor or celling	Walls can be straighten up to be perpendicular to the floor, ceiling and walls

* Calculated on a 0.2 x 0.2 meters surface

The accuracy level give the BIM provider an accuracy expectation to the final product. Both data capture and the modelling work is covered. Based on the accuracy level the provider can select the most cost efficient method to capture the data. One of the important messages in Table 1 is that you do not need a level 1 scanning if you during modelling will straighten up walls, floors and ceiling to ensure that they are perpendicular. This count if your intention is to use your model in further work and not the point cloud.

Table 2: Information contend in BIM model, gives an overview of 3 different level of detail

Level of Detail (LOD)	**Class A**	**Class B**	**Class C**
Description	*Full BIM*	*Slim BIM*	*BM (overview)*
Relative content of information in BIM	Volume model, standard objects with attributes and relations	Volume model, standard objects *Defined (limited) information*	Volume model

The next step is the integrated processes. In this step, the measurements become a real BIM. Again, it is important for the buyer to have a conscious relation to the content of the BIM. A simple volume model is cheap, and this is classified as BIM class C. If you add standard objects, it is more expensive and more useful. Finally, if you add attributes and relations you get a full BIM and BIM class A.

Table 3: Framework for Purpose BIM

Accuracy level / **BIM class**	**Level 1**	**Level 2**	**Level 3**
Class A	Multiple purpose (Expensive)		Limited purpose (Moderate price)
Class B			
Class C	Limited purpose (Moderate price)		Single purpose (inexpensive)

Table 3 illustrate the relation between the cost and applicability based on the criteria accuracy level and BIM classes. The highest accuracy product is level 1. If you combine this with the BIM class A, you get the most expensive product. BIM class A gives you a BIM with standard objects with attributes and relations. On the other end of the scale, you find accuracy level 3 and BIM class C. This is the cheapest product with less accuracy and no building objects. The accuracy level 1 has the highest flexibility. With high flexibility, you have the opportunity to change your BIM from an accuracy level 1 to accuracy level 3. You also have the opportunity to change from BIM class A to C and vice versa. If you create your BIM with the accuracy level 3, you are not able to change you BIM to the accuracy level 1 without new measurement, but the BIM class can be change. This means that accuracy level 3 has a lower flexibility than accuracy level 1.

Table 4: Framework for Purpose BIM examples

Accuracy level / BIM class	Level 1	Level 2	Level 3
Class A	Rehabilitation		Facility management
Class B			
Class C	Absolute documentation of geometry		Volume sketch and planning

Table 4 illustrate which purposes, which accuracy level and BIM class are suitable for some example purposes.

5. Examples from the case study

The case study used in this paper is based on a project in Oslo, Norway. The building was built in 1890 and has a co-ownership organization with 16 different sections. A board selected by the co-owners controls the building. An important aspect was distribution of cost related to the total area of each section. The area of each section was unknown. It was disused to use the existing drawings to create the BIM. The problem was that the drawings where old and did not give a correct picture of the areal situation. Another problem was that the basement was not present in the drawings. The boarder also had maintenance tasks waiting ahead where they would like to using a BIM. The dream was to link the maintenances history, the today's status and scheduled maintenance directly to building objects in the model. Additionally they needed a fire and evacuation plan. They also had a project where they needed to control the chimneys. Based on these needs the scan to BIM project was started. The Norwegian Building Authorities was interested in the project and decided to finance the project. The company Rendra won the project after public announcement. Rendra has developed an application for interoperability in construction projects based on BIM. Sweco BIMlab consulting engineers performed the measurement and modelling of the building. The data capture and modelling was scheduled to take 5 weeks. The static point based laser measurement called Flexijet 3D 4ARCHITECTS was used for data capture. The system is directly linked to Archicad, which means that the BIM is created directly on site. The total budget for the project was 200 000 NOK (approximately 22.000 €).

The result from the project was good. The boarder got a BIM they could use for area calculation of each section, storage room in the basement and storage room in the attic. This solved an ongoing conflict in the basement. From the BIM they can extract drawings like fire and escape plans, extract volume of the walls, framework to store information about the past, present and further for each building object. The new established BIM is a good starting point to establish a maintenance plan (DIBK, 2015).

In the evaluation of the BIM one of the section owners discovered that his apartment was 10 m2 larger than the report form the latest valuer report (DIBK, 2015; chapter 4.6). It is likely that the areal in this report has been calculated with a tape measurement device, manual or digital. It is therefore likely to claim that the BIM provide the correct area calculation. The price pr. square meter in this area is higher than 50 000NOK (5400 €). This has a big influence on the value of the property.

The experience from the project shows that it is very time consuming to arrange access to all the different sections. Sweco BIMLab performed the measurement and informed that 25% of the time was used just to get access to the different sections DIBK (2015, chapter 4.7). In the evaluation of the result, the board claim that the model has a higher quality and richness than they actually needed (DIBK, 2015; chapter 4.3). There are for instance more objects present than they expected. This model is therefore a good opportunity to use the BIM for more purposes than initially intended.

We have concluded that it would have been beneficial to use a data capture method, which use less time on site and more time in the office. The main reason is that approx. 25% of the time was spent on getting access to the different sections. Flexijet scanning contain only what has been presented in the model. There is no extra data for further processing. This makes the method sensitive for missing registrations and it is difficult to document the quality of the model.

Table 5: Identification of possible purposes for the example case

Accuracy level / BIM class	Level 1	Level 2	Level 3
Class A	No Possible expansion	No Possible expansion	No Possible expansion
Class B	No Possible expansion	Case study	Possible expansion
Class C	No Possible expansion	Possible expansion	Possible expansion

The case study have an accuracy level 2 and a BIM Class B. Table 5 illustrate which direction it is possible to expand the BIM. The main reason for this limitation is the Flexijet method where you collect limited amount of data. It is not possible to enrich the model without revisit the building. If a “more is less approached” had been use it might have been possible to enriched the BIM without revisit the building. Then all BIM classes with accuracy level 2 and 3 would have been an option for expansion. If we assume the same starting point. This is illustrated in Table 6.

Table 6: Possible purposes for the example case collected with a "more is less approach"

Accuracy level / BIM class	Level 1	Level 2	Level 3
Class A	No Possible expansion	Possible expansion	Possible expansion
Class B	No Possible expansion	Case study	Possible expansion
Class C	No Possible expansion	Possible expansion	Possible expansion

6. Discussion

This concept paper is based on a literature overview of available technologies within hardware for scanning and software for processing captured data, in addition to use a real project as case. The practice of today is driven by use of technology offered by the selection of services from the scan to BIM provider. The proposed "purpose BIM" framework intent to enable an overview of applicable technology for capturing data, and by processing the data into BIMs applicable for multiple purposes. Overview of technology, process and competency (with reference to the trinity in the IDDS framework) enables the building project owner to manage the scan to BIM process by ordering or purchasing process. This study is therefore not a study of selecting the best technology, but how different technologies can be combined to enable a potential for multiple purposes in the future based on reuse of previous work (normally done at low additional cost as supplement to the primary job, e.g. a cloud scanning, when doing point scanning).

A real case was used as example for the scan to BIM process to explore how the "purpose BIM" can be applied. However, further empirical studies are needed to assess the reliability of the framework, in addition to further detailing and guidance. We have focused on accuracy level in the data collection, accuracy in modelling and the level of detail in the building objects. Especially the level of detail is general and need further detailing. In a comprehensive product specification, it will be necessary to have a full list of objects, which should be included in the model. It is also necessary to define which attributes and relation each object should have. In a complex building, this list may be long and complicated. If possible, it will be an advantage to create general rules instead of a complexed list. The comprehensive product specification is important to make sure that the model is created and enriched according to the contractor's expectation. Additionally the providers have the possibility to calculate the cost more precise. This will contribute to a more fair competition situation where the provider know precisely what to deliver.

7. Conclusions

This study has introduced the “Purpose BIM" as a framework to support flexible ordering of services to solve multiple purposes at positive cost/benefit. This framework structure the ordering processes to combinations off accuracy level from scanning related to BIM classes for processing of scanned data for defined purposes and potential purposes.

An overview of technology and services is presented and illustrates possibilities for a more flexible process. Detailing the overview by current commercial solutions is recommended before practical use. On the other side, we see that the Purpose BIM as a framework will become more relevant to enable increased numbers of solutions by combining technology and processes and personal resources. An important aspect is to break-down into small work-packages or services that can act as options for further processing and enabling of new purposes.

Development of technology will increase the possibilities to combine various technologies at low cost and enable possible multiple use. This will be a key factor to make it common to use BIM in the facility management. With lower prices and flexible processes, the purposes can be extended to purposes we have not thought about or minor tasks, which normally are taken care off in a manual way. One key aspect in this framework is to set up development and feasibility plan to ensure a multiple purpose BIM. Another key aspect is to use the purpose BIM framework to select technology and process to maximize the cost /benefit ratio.

From BIM to CIM to Innovate Life Cycle Management of Entire Works and their Parts

Sonia Lupica Spagnolo

Politecnico di Milano, Italy
Email: sonia.lupica@polimi.it

Abstract

During the last few years, many efforts have been made to promote the widespread use of Building Information Modelling (BIM) and to exploit its potentialities. Despite several important activities at international level aimed at creating standards, free tools and open languages for interoperability, the BIM approach has mainly brought enhancements to software for 3D renderings which now are able to represent complex models where information is directly associated to each object constituting the model itself. However, the exchange of information among different stakeholders has not improved significantly, most of all because real interoperability among software has not been achieved and because data sharing has to be independent of specific commercial software.

Along different life cycle stages, asset and facility management represents a very interesting field for the application of BIM strengths because it needs to store and use much information about the behaviour over time of different building materials, products and components. Moreover, because at international level (for instance, CIB W080 Commission is still working hard on this aspect) the lack of reliable tools for service life planning and data capitalisation from facility management is evident. It is then necessary to develop some methods for Service Life Planning and Management, to be easily integrated by maintenance data and used during the design of facility and maintenance activities. Therefore, only the development of specific Information and Communication Technology (ICT) tools for life cycle data use and sharing based on Industrial Foundation Classes (IFC) standards of the International Alliance for Interoperability (IAI) can actually enable exploiting BIM potentialities along the entire building process.

The paper presents a number of activities undertaken in the last few years by Politecnico di Milano in order to move from a BIM approach (where the modelling is central) to a Construction Information Management (CIM) system capable of allowing an effective integration and exploitation of building process data along the entire life cycle of construction works and their parts.

Keywords: Maintenance, facility management, Service Life, Life Cycle management systems

1. Introduction

Service life planning and data capitalisation from facility management are only the first steps for an efficient asset and maintenance management because it is necessary to develop specific ICT tools for life cycle data use and sharing [Daniotti et al. 2015]. Without an integrated information managing system, it is difficult to gain exhaustively each necessary input data and it may affect a correct maintenance planning and management. This causes a waste of money and time, but it can also decrease the effective control on the sustainability of the building process itself: for example, without the knowledge about laying procedures, in-use condition or end of life interventions for the specific construction site, the choice of sustainable products could be frustrated and Life Cycle Assessment (LCA) be incomplete.

That is why, in the last few years Politecnico di Milano has undertaken research activities in order to develop on one side an international platform for durability management, supported by reliable methods for Service Life estimation, and on the other side a national prototype of database for an efficient data exchange among different stakeholder of the construction chain. The adoption of the same object approach to the entire construction field (not only buildings, but also infrastructures, services, processes and anthropomorphic environment), together with sharing information independently from the model, allowed the creation of a Construction Information Management (CIM) system.

Hereafter the description of these two important tools, which in the future could be merged together in order to build a unique and interoperable platform to innovate life cycle management, capable to store objects with different level of complexity (from simple products to entire construction works).

2. The international platform for Service Life appraisal, data storage and sharing

As mentioned, Service Life planning is important in the design step because the set of taken choices must be influenced by the entire life cycle assessment of a building process. Moreover, the choice of the most suitable building components and materials to adopt has to consider not only their duration but also their failure rate curve over time: an effective sustainable process depends on an optimised maintenance planning and this is possible only through the knowledge of building components' durability. Consequently, the need for more accurate Service Life data is essential, compounded by the necessity of a wider availability and an easier accessibility to such information. That is why, through the analysis of the necessary data to allow designers evaluating duration and planning maintenance, CSTB (Centre Scientifique et Technique du Batiment - the French Scientific and Technical Centre for the Building Industry) and Politecnico di Milano structured the French Reference Service Life (RSL) database [Hans et al. 2008].

Such a database contained some input data necessary to ICT tools for Service Life management and, therefore, became the starting point for integrating results from past research activities and developing new research programmes to enhance and make it usable at international level [Daniotti et al. 2008].

The realisation of an international database involves the need to use a classification for building components and materials that could be valid beyond French and Italian borders and available for further implementations. A unique and efficient communication tool demands a standardised description of building objects that makes easy the communication among different subjects: in the construction field, this facilitates a faster individualisation of characteristics, a proper organisation of each set of documents and, eventually, reliable costs evaluation, time scheduling and sustainability assessment.

This classification system must have two essential characteristics in order to be proper for this purpose:

- to individualise univocally each family of objects and to allow every further piece of information to join in order to describe precisely each object;

- to be applicable to every class of objects, independently from its complexity.

Since the base of a classification system is the partition of a series of elements in classes, there are two different ways to group various elements:

- a direct grouping: elements are identified as belonging to a class, classes are organised according to a hierarchical order, so there are some main classes and, for each of them, some sub-classes and so on; for instance, the parts of a building are walls, floors, foundations, the roof, etc.; inside these groups, it is possible to identify other elements; an example of classification based on a direct grouping is MasterFormat, which is widespread in the USA and Canada;

- a combined grouping: there are different attributes for an element and this is identified by the free aggregation of these attributes; examples of this classification are the SfB and the Italian standard UNI 8290.

The first activity that was undertaken was to define the most proper classification system to adopt: therefore, it was necessary to fathom and study, first of all, existing classification systems adopted all over the world (Figure 1). This preliminary analysis showed the difficulty in classifying every construction element in an univocal way and, above all, a great fragmentation of these systems .

Consequently, it was necessary to propose and adopt another classification system that could be used at international level for the RSL database.

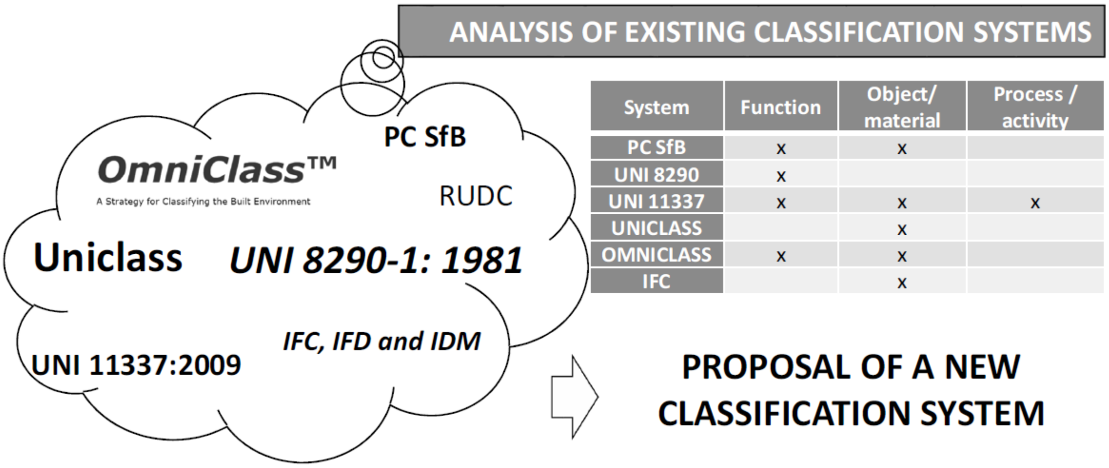

Figure 1: Comparison between existing classification systems

The SfB classification (Swedish acronym of Samarbetskommittén for Byggnadsfrägor - Cooperative Committee for Construction Issues) was born in 1956 with the objective to become an implementing classification system at international level. Realised in Sweden, it was presented in Holland in the presence of many experts from all over Europe. The first English version was translated into German and Italian. In spite of this transnational peculiarity, SfB classification has not been used on a large scale.

Another exception to local classifying systems is RUDC, part of UDC (Universal Decimal Classification) which was not directed toward the construction field, but to organise every kind of information.

The Italian standard UNI 8290 of September 1981, aimed at standardising the terminology to employ, represents an important step in supplying at national level a classificatory model, which gives, in the field of residential buildings, the classification and the articulation of technological units and of technical elements in which the technological system is divided.

The Construction Project Information Committee (CPIC) introduced the UniClass (Unified Classification for the construction industry) system in the United Kingdom in 1997 and it suggested a method for the building sector classification based on 15 tables. Each board looks at a specific information aspect and it can be used separately or linked together with other tables to express complex concepts.

MasterFormat represents the standard of communication more used in USA and Canada to organize the project contents and the relevant documents. The project, through the Construction Specification Institute (CSI) proposal, can be split into divisions and sections, with the aim of standardising a procedure to manage every type of project information.

OmniClass is a classification system that was accepted by the US building industry in 2006. It is a freely available standard based on a common language for the whole building sector and a standardised system to classify information regarding the entire building life cycle, from planning to demolition.

Eventually, the Italian standard UNI 11337:2009 introduced a new framework approach to classify contemporarily functions, objects and processes/activities. It organises a list of items according to the logic of the works carried out, in order to permit analytical evaluations (as the cost per measurement unit for each intervention required by each work) and elementary evaluations (as the cost per measurement unit of technological units).

Therefore, for the international RSL database a new classification system was adopted: it is based mainly on SfB classification, UNI 8290 and UNI 11337:2009. As the necessity was to allow a collection of RSL data for building objects, this proposal does not contain the classification of activities, vehicles, tools, human resources or environments. For example, it can be used to individualize univocally a pillar, but not an activity like daubing, a vehicle like a crane, a tool like a trowel, a person like a bricklayer or a place like a kitchen.

Politecnico di Milano contributed not only to RSL definition, but also to create some grids for the application of Factor Method [Daniotti et al. 2010], considering moreover the elaborations on statistical basis lead on the climatic agents for accelerated ageing cycle definition [Daniotti et al. 2008]. As a consequence, the database for RSL collection became necessary not only for the convergence of all the information coming from the experimental researches, but also to constitute an indispensable tool for the application of existing methods for SLP (ISO 15686-2 and UNI 11156-3) and, in particular, of the Factor Method.

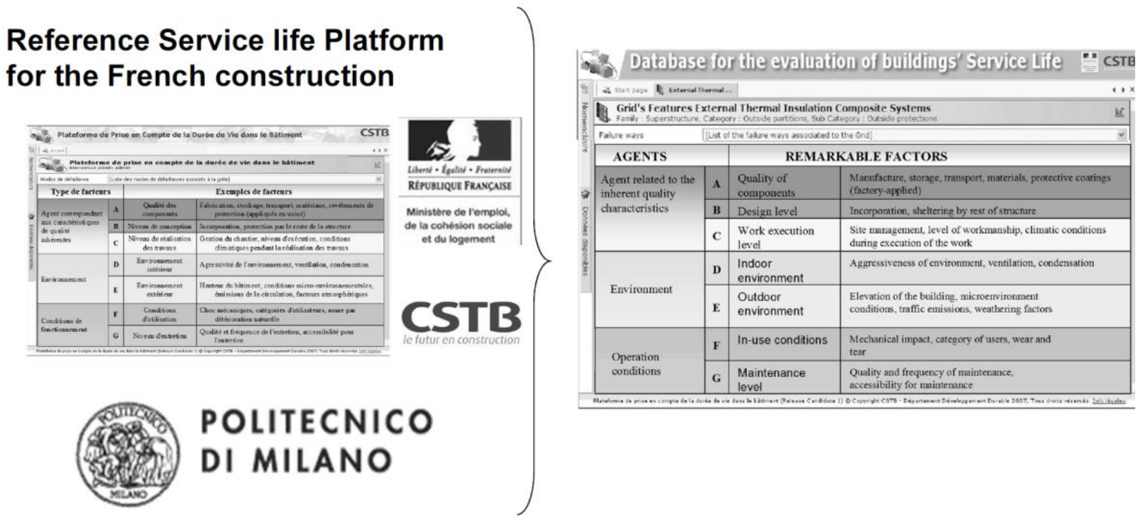

Figure 2: From the French National RSL database to the international durability platform

To do that, each single building component is associated to a specific factor grid, which translates all the variables affecting Service Life into different sub-factors belonging to the seven main factors proposed by ISO 15686 Factor Method. Thus, the construction procedure of the database consists of four main steps, namely:

1) a grid is built for a given building component by a panel of experts;

2) the grid is shared among the stakeholders of the construction sector;

3) information regarding properties and service lives is collected by the stakeholders for the comprised sub-factors;

4) data are validated by the platform administrator.

3. INNOVance, the Italian database for Construction Information Management

Another step forward in evolving the BIM approach, through Building Information Modelling and Managing (BIM&M), towards CIM was made by Politecnico di Milano together with many important partners (Figure 3) during a three-year research project called INNOVance.

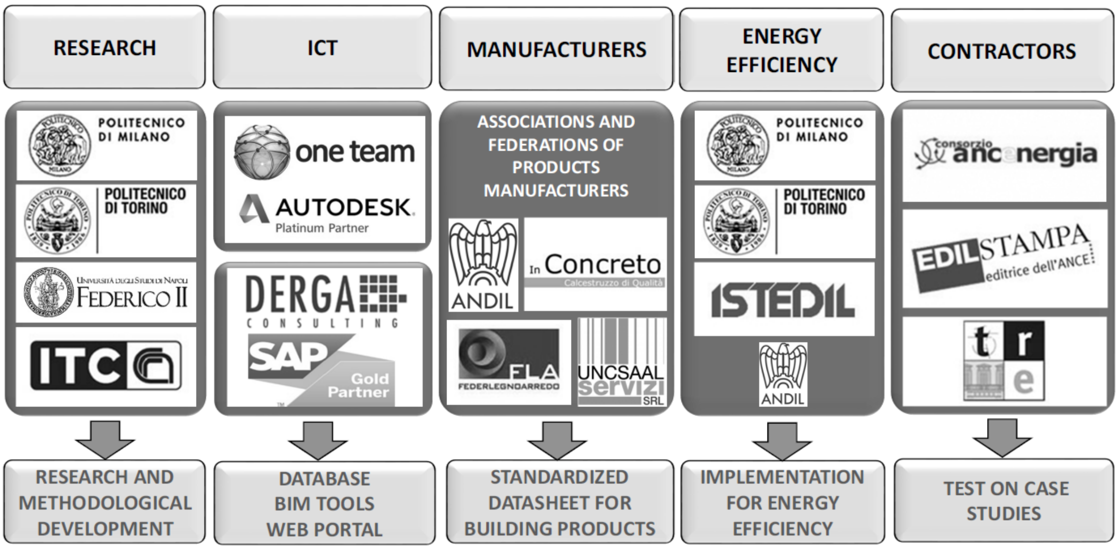

Figure 1: INNOVance partnership

This research project, funded by the Italian Ministry of Economic Development, started in July 2011 with the aim to introduce a radical innovation into the Italian construction sector by creating the first national construction database and a prototype of interoperable BIM&M platform (Pavan et. al 2014).

To overcome possible inefficiencies due to incorrect or redundant exchange of information among actors of the construction chain throughout the entire life cycle of a work, Politecnico di Milano developed a new classification, naming and coding system that allows speaking an unambiguous language where synonymies and all the different meanings of the same word are clear and already defined [Daniotti et al. 2013]. The naming and coding system developed with INNOVance takes into consideration the entire construction work as the last output of the construction industry, analysing it from five points of view (Figure 4):

- the functional-spatial logic in order to highlight environment and functional areas in which the construction work is divided (for example, commercial areas inside a building);
- the technological logic for construction in order to disassemble it in its elements, from entire components to single products;
- the technological logic for equipment in order to disassemble it in its parts, from entire systems to single products;
- the anthropomorphic logic to represent all the changes on environment and those natural aspects related to it (e.g. excavation and embankment);
- the processual logic to individualise and codify activities, vehicles, tools and human resources.

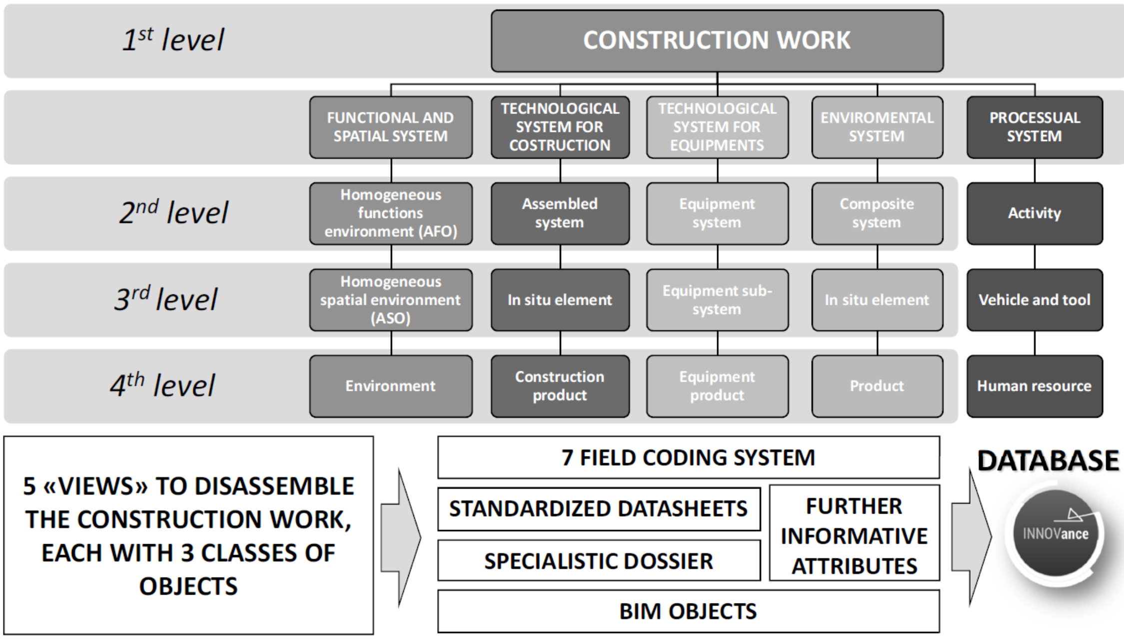

Figure 2: INNOVance hierarchical structure

Each of these logics contains three levels of objects, according to their complexity. Considering this hierarchy, the adopted coding system then defines a structure with an open compilation and seven fields, which can describe every element to be encoded, independently from the object complexity and the set system to which it belongs (Figure 5):

1. category;
2. type;
3. functional and in use characteristics or, for construction products, harmonised technical standard;
4. performance characteristics;
5. geometrical features such as geometry, shape, aesthetic and constructive traits;
6. dimensional features;
7. physical / chemical properties.

The reason for the choice of a fixed seven fields coding system is to standardize the output code and to a have a coherent individualisation of each information inside the code itself.

7 FIELDS CODE, INDEPENDENTLY FORM THE OBJECT COMPLEXITY						
Category	Type	Functional characteristics/ Harmonized technical standards	Performance characteristics	Technical characteristic		
				Geometrical features	Dimensional features	Physical/ chemical properties

Figure 3: INNOVance coding system

Talking the "same language" with a common classification and coding system allows avoiding communication errors especially during design and construction. However, this was not enough to innovate the life cycle management. The second step was, therefore, to create a tool with a standardised procedure for data sharing to avoid misunderstanding, errors, over costs and delays, mainly due to documents and drawings that are not correctly interpreted and updated.

Consequently, exploiting the unambiguous classification system for every object and the defined hierarchical structure, Politecnico di Milano, in collaboration with Derga Consulting S.r.l. (a partner of SAP, acronym for System, Applications and Products, a software company which developed some Enterprise Resource Planning and data management programs) created a unique database to store and share information. This ICT tool allows collecting, for each object individualized in the above-mentioned hierarchical structure:

- standardised datasheets and specialised dossiers, with every useful document (images, videos, drawings, etc.) that can be easily enclosed;
- further informative attributes which cannot take place in the defined datasheets and dossiers;
- BIM objects in different file formats (among which, the interoperable IFC format).

Figure 4: Web portal homepage

A SAP ERP system (SAP NetWeaver) contains all the structured data. By unequivocal names, technical datasheets, specialised dossiers, complementary data and BIM objects, all organised in the INNOVance database and accessible by a user-friendly web portal (homepage in showed in Figure 6), each user can manage his projects, since the design brief and through all the further phases.

Through this website, many operations are possible: for example, manufacturers can create, upload and modify their construction products standardised datasheets, adding BIM objects too, designers can describe the technical solutions designed and share their projects; companies can consult data sheets established by designers and manufacturers, checking the correspondence between ordering and arrival of the goods.

The web portal constitutes an exchange platform (Figure 7) with:

- a public section, open to any user, where it is possible, for example, to find a BIM Library, and where information (graphical, alphanumerical or multimedia) is embedded into Generic BIM Objects (out of a specific context);
- a private section, open only to logged users, where it is possible to store a personal library of datasheets and dossiers and where, thanks to the so called BIM&M Server, in any stage of the construction process, they can convert generic BIM object from the BIM&M library into Specific BIM Objects (in a specific context).

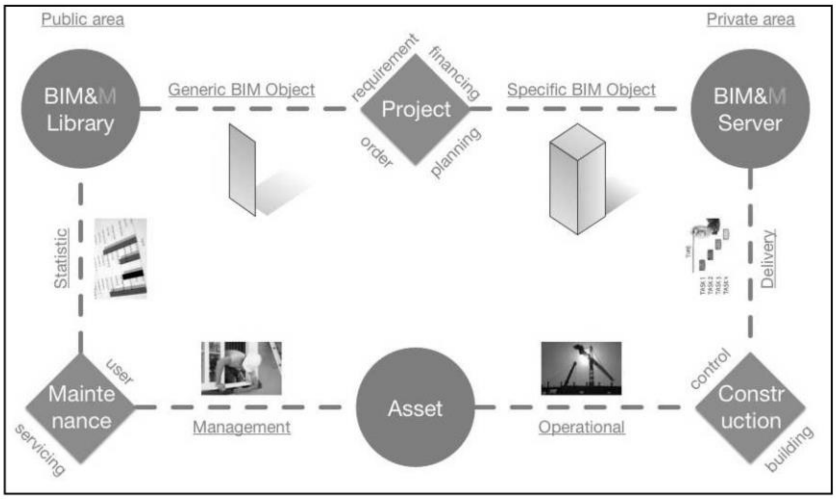

Figure 5: INNOVance system workflow [Pavan et al. 2014]

This web platform aims at becoming an interactive footbridge among different stakeholders. To do that, as the quantity of collected information will be huge, there are different views of the database according to the user's profile: this facilitates its use, filtering only useful data for the considered stakeholder, but leaving the possibility to search, visualise and, possibly, modify any other information of the database.

4. Conclusions

Asset and facility management needs to store and use much information about the behaviour over time of different building materials, products and components. Service life planning and data capitalisation from facility management are only the first steps for an efficient asset management because it is necessary to develop specific ICT tools for life cycle data use and sharing.

A strategic step toward the optimisation of both the building process and the whole construction sector is represented by a rationalisation of the information flows connecting construction process stages (planning, design, construction, use, management, maintenance, disposal or reuse) and the various actors involved (customers, users, designers, contractors, components manufacturers, etc.).

Starting from the expertise in developing the above-described international Reference Service Life database, Politecnico di Milano structured a complete Construction Information Management system: the INNOVance platform. This constitutes a unique collaborative tool, meant to store, elaborate and share every useful data along any building process and to support every actor involved in the process. Impacts on the entire construction field are evident: by its adoption and use, it is in fact possible to avoid misunderstanding in communication and redundancies in data, increasing the efficiency of building process along the entire life cycle of each construction work because the exchange of every information is associated to unique codes in a fast, interoperable and reliable way.

A Case Study of Building Information Modelling Enabled 'Information Totem' for Operations and Maintenance Integration

Erika A. Parn, David J. Edwards and Richard Draper

Birmingham City University, UK
Email: erika.parn@bcu.ac.uk

Abstract

This paper reports upon the use of a semi-automated toolkit to aid the development of as-built Building Information Model (BIM) (As-built model reflects on-site changes by the contractor to the original BIM) from inception to final construction. An observational case study of two educational 'multi-storey' facilities obtained primary data from project archives and focus group meetings with key design team members. The results demonstrate that the data requirements for both structures evolve post occupation because of stakeholder tacit knowledge accrued via building operation and usage. The semi-automated toolkit developed can readily access operations and maintenance (O&M) manuals, retrieve room specific data (such as categories of equipment or building element) within the as-built BIM and, assist in the navigation and coordination of amendments and changes throughout the construction phase. This paper provides useful practice-based information for practitioners to develop suitable BIM data structures for future information requirements throughout a building's lifecycle. The inherent value of the semi-automated toolkit resides in the facilitation of ease of handover for the Facilities Management team during the O&M stages.

Keywords: As-built model, BIM, Facilities Management, Operations and Maintenance, Maintenance management

1. Introduction

Succar (2009) defined Building Information Modelling (BIM) as a: *"procedural, technological shift within architecture, engineering, construction and operations."* This definition was expanded upon by Eastman *et al.*, (2011) who noted that BIM has shifted the way building information is managed, exchanged and transformed to enhance collaboration between project stakeholders. Garber, (2014) concurred with this view and suggested that BIM provides a platform for better design team integration and project coordination. From an operational perspective, BIM embeds key product and asset data, and a three-dimensional computer model that can be used for effective management of information throughout a project's lifecycle from earliest concept through to occupation and use (HM Gov, 2012). Consequently, BIM deployment throughout the building lifecycle is invaluable to organisations that seek to obtain value from the technology (Love *et al.,* 2013; 2014). In essence, BIM represents a collaborative way of working, underpinned by digital technologies, which unlock more efficient methods of designing, creating and maintaining assets (HM Government, 2012).

Khemlani (2011) states that every constructed facility requires a bespoke BIM model, analogous to an owner's manual, with mandates for model updates that correspond to periodic repair, or refurbishment works. In practice, BIM in the operations stage has been primarily connected to the roles and responsibilities of the Facilities Management Team (FMT) but this can create problems in other areas (Becerik-Gerber *et al.,* 2012; Volk *et al.,* 2014; Kassem *et al.,* 2015). For example, Teicholz, (2013) reported upon a litany of issues which include: inconsistent naming conventions used; a myriad of bespoke FMT information requirements; inadequate data categorization in BIM and computer aided facilities management (CAFM) systems; poor information synchronization; and lack of methodology to capture existing facilities and assets. Delivering efficient operations and maintenance (O&M) procedures for buildings is therefore problematic and exacerbated by the vast complexity and volume of data and information generated (Mohandes *et al.,* 2014).

The open access digital environment afforded by BIM provides a partial solution to this issue because it readily affords storage, sharing and integration of information for future use. Indeed, contemporary research demonstrates promising potential for integrating facilities management (FM) within a BIM environment at the post construction stage (Azhar, 2011). In aiming to characterise the hybrid BIM-FM environment, Kelly *et al.,* (2013) observed that the following advantages could be accrued, namely: augmented manual processes of information handover; accuracy of FM data; and increased efficiency of work orders execution to accessing data and locating interventions. However, the construction industry currently resides within a transition period of adopting BIM. Industry practitioners are now selecting their own paths to cope up with the new technology in this rapidly changing environment and climate of exponential technological advancement. To date there remains a considerable dearth of applied studies that develop a hybrid BIM-FM environment and/ or report upon the tangible benefits of such to practitioners. With this in mind, this paper proposes a semi-automated toolkit (also known as an *information totem*) to aid the development of as-built BIM from design to final construction. A conceptual design for the toolkit is presented and is based upon a case study of two multi-storey educational buildings augmented with pragmatic input from the building's FMT.

2. BIM Value for FM

Contemporary literature indicates that exploiting BIM's inherent value adding capability within a building's development remains questionable especially, during the transition period of adopting BIM within the project's whole lifecycle (Parn *et al.,* 2015). Despite the palpable benefits of BIM application during the design and construction stages, case-studies of its application during the management and maintenance of assets during the O&M stage of building occupancy remain scant (Kelly, 2014). Yet, Boussabaine and Kirkham (2008) reported that 80 percent of an asset's cost is spent during O&M, leaving the benefits of BIM short lived at the design and construction stages. In addition, Love *et al.,* (2015) suggests that significant challenges are presented by an ill-equipped project team who lack standardized tools and processes, specific data required for operations and, maintenance and the workflow to deliver a digital model.

As a 3D modelling tool associated with a parametric database of components, BIM offers the FMT opportunities to manipulate and utilise information contained within 3D objects (HM Government 2013). However, Liu and Issa (2014) found that during the design phase, participants in a BIM project focus on clash detections and tend to ignore future-proofing maintenance accessibility. The authors (*ibid*) highlighted potential in BIM for designers to explore the background geometry and parametric database to add functions to help the FMT anticipate and solve maintenance accessibility issues. Similarly, Meatadi *et al.,* (2010) and Motawa and Almarshad (2015) proposed additional tools to improve BIM's performance at the O&M stage by effectively engaging stakeholders. Longstreet, (2010) further added that the value of implementing BIM increases exponentially as a project lifecycle unfolds. This is because BIM value in FM stems from improvements to: current manual processes of information handover; accuracy of FM data; accessibility of FM data; and efficiency increase in work order execution (Kassem *et al.,* 2015). Consequently, FMT involvement during the BIM development process is essential because they can alert the building delivery team of any issues related to O&M of facilities. This synthesis of extant literature underpins the necessity to involve building operators/ management stakeholders in the design phase of a BIM project. Interestingly, Bosch *et al.* (2015) contradicted this position and concluded that the current added value of BIM in the operations stage was marginal due to a lack of alignment between the supply of and demand for FM related information and the context-dependent role of information. Although the antithesis of Bosch (*ibid*) is contrary to opinion within main stream literature, Kassem *et al.,* (2015) did concede that a key challenge of BIM-FM integration is a lack of methodologies that demonstrate the tangible benefits associated with this hybrid merger.

3. As-built BIM Model Structure to Aid O&M

At the O&M stage, more than 80% of a FMT's time is spent on finding relevant information because such expenses are often overlooked at the pre-construction stages by designers (Becerik-Gerber *et al.,* 2012). Consequently, a number of studies are supportive of BIM application within the O&M stages (Patacas *et al*., 2015; Motamedi *et al.,* 2013; Volk *et al.,* 2014). This is because BIM provides an information conduit and repository (containing for example, manufacturer specifications and maintenance instructions linked to building components) in support of building maintenance management activities (Sabol, 2008). Such information and functionality is important when handing-over an accurate as-built model to building owners for the purpose of asset management. At present, laser scanning represents a common methodology used to create an as-built model of the completed project (Bennett, 2009). However, this methodology is time consuming and prone to human error and hence, as built preparation is perceived to be a time consuming and costly procedure (Huber *et al.,* 2011). The Institution of Civil Engineers (ICE) (2015) state that these issues can largely be eliminated through the provision of a reliable, BIM-sourced suite of information. However, the technical expertise of the FMT represents a significant barrier to BIM and as-built model development and maintenance (Kassem *et al.,* 2015).

McArthur (2015) suggests that identification of critical information required to inform operational decisions is a critical determinant towards configuring data retrieval techniques at the post-construction stages. Despite being emphasised by a number of authors (Meatadi *et al.,* 2010; Motamedi *et al.,* 2013), the issue of identifying critical information and linking them to the as-built model for O&M phase usage remains problematic. Meatadi *et al.,* (2010) revealed that the inconsistency between demand and availability of particular information in an as-built model incur unnecessary expenditures. Thus, linking data and configuring the retrievable information within the as-built model for the project's post-construction operational phase is a key issue that must be considered during the design and development of the BIM data.

4. Problem Domain: Big Data Acquisition

When utilising BIM technology, a vast array of data (commonly referred to as *big data*) is produced and integrated into existing objects within the 3D BIM (Bentley, 2003); where big data has been defined as high volume, velocity and variety data sets which pose extreme data management and processing challenges (Laney, 2001). Data within the model requires a structured method of information and data categorisation that can be tracked, validated and extracted. Grilo *et al.,* (2010) argue that BIM should create a broader base for interoperability in order to be fully utilisable, such as standards on communication, coordination, cooperation and collaboration. The huge volume of data within an as-built model is a matter of concern in terms of extracting valuable information and knowledge from it during the O&M phase of a building, particularly for the FMT (Russom, 2013). Federated models are defined as the amalgamation of multiple models in one, namely: architectural, structural and MEP models (HM Gov, 2012). To further exacerbate this issue, not all data is contained within one federated model because the FMT often link BIM to additional relevant external databases, to create a highly integrated multi-dimensional model (Succar, 2009; Love *et al*., 2015). This mass of data creates opportunities for new thinking and/ or adopting alternative techniques for model data structuring (Bentley, 2003). Matthews *et al.,* (2015), explored adaptation of cloud-based technology with object oriented workflow for as-built BIM scheduling. In a similar vein, this research adopts an 'object-orientated workflow' for real time data capture. However, the semi-automated toolkit proposed will predominantly be used to capture changes relevant to the FM parameters embedded within *information totems*. Information totems provide an additional layer of information structuring that are fed through to the federated as-built BIM model congested with high volume of data loads.

5. Methodology

This observational case study largely relied on project archival data and focus group discussions to explain as-built BIM preparation and the development of information totems. Specifically, the research sought to observe and report upon the processes and procedures adopted during the development of the as-built BIM to facilitate ease of handover for the FMT. Two multi-storey educational buildings located in the centre of Birmingham, UK were used for this study. Building one was build first and constituted phase I of the development and building two was built second and constituted phase II. Primary qualitative data was collected using verbal interviews with key stakeholders which included representatives from the project management team (PMT) including the client's representatives (i.e. the Building's Estates Department) and design related disciplines (including the Architect, the Contractor's BIM Manager , Principle Designer for Mechanical Engineering and Plumbing and the Lead Structural Engineer). Note that the Estate's Department held three fundamental roles, namely that of: client's representative; project manager; and Estates Department and hence, covered all three major phases of the building's life cycle. Two meetings were held with the PMT over a 4 months period during 2015. Secondary data sources further complemented information obtained and consisted of project documents including contracts, bids, BIM execution plans, EIR's and BIM protocols. Additional hand written notes were taken to record impromptu meetings or telephone calls held. Largely archival records of BIM documentation and contracts provided: i) an elaborate account of contemporary practices through the exploration of stakeholder experiences and interrogation of the images themselves; and ii) sponsoring organisations with opportunities to learn from everyday experiences of design team members and the FMT. During the study, FM associated aspects of BIM implementation were observed to evolve as a consequence of a synthesis of diverse opinions emanating from the PMT.

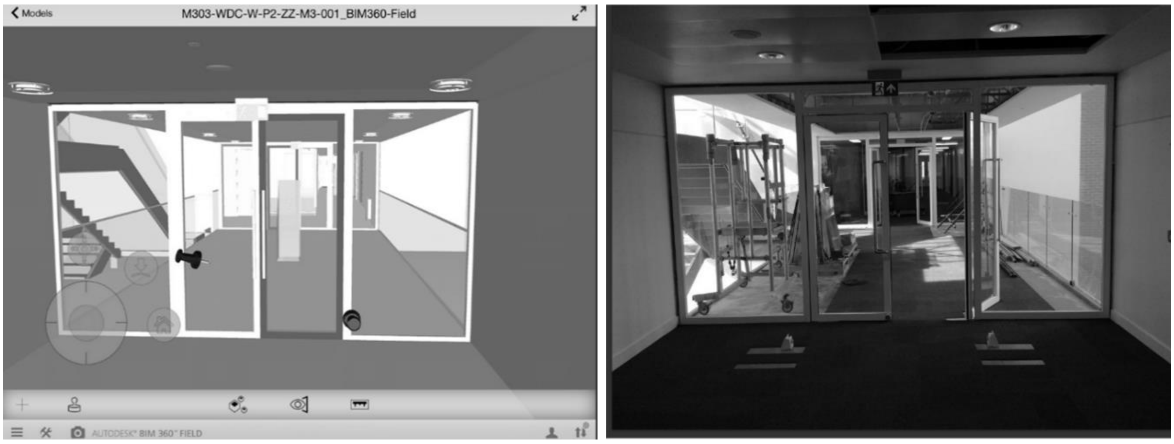
6. Case Study Discussion and Findings

Individual PMT group members claimed to have been inexperienced at utilising BIM technologies the outset of the project's development during phase I. However, at the end of phase I team confidence grew, and the idea for an information totem was conceived and proficiency/ competency gains were adopted in phase II. Information totems were described by the PMT as a placeholder for the room datasheets used during O&M stages of a development and are used for data input and retrieval. When formulating the information totem concept to ensure BIM and O&M data integration, the PMT considered various outcomes including: modelling requirements for FM; and model structure for data retrieval. The aim being to generate an information totem that would deliver interoperability and encapsulate the following attributes: i) increased of coordination; ii) facilitated ease of communication link; iii) informed decision making; iv) enabled information exchange enabler between multiple stakeholders; and v) provided ease of navigation between BIM model and construction site. Different PMT members added room specific information into each totem; contractors then retrieved asset related information for guidance during the construction stages and attach construction progress photos to each totem. Data within totems was predominantly categorised into FM parameters, were often room bound and in the instances of open plan spaces, these divisions of space were allocated by the PMT during the building's design. The totems themselves connected to multiple external data bases which are directly linked with room specific O&M manuals, maintenance frequency codes for different spaces and product fact sheets.

6.1 Asset Management at O&M stages

During the O&M phase, the client used of room barcodes (Figure 2) to aid the management of assets by allowing efficient access to data at the O&M stages. This same barcode was applied within information totems and mapped into FM software utilised at later stages of the development, including the cloud based BIM platform used for both projects.

Figure 1.Infromation totem for site navigation



(a) *(b)*

a) View of the Information Totem in yellow from the cloud based federated BIM model. b) Photograph of the same location on site as cross reference retrieved from the information totem.

Figure 2. Asset Management with room barcodes

(a) *(b)*

a) A Barcode tagged room in Phase II, barcodes are typically placed outside the rooms on doorframes. b) Individual steel barcode plates, typically an 8 Digit number bi-directionally linked with the information totem held in the federated model. These barcodes associated per room are used by facilities management team for ease of access to the digital O&M manuals and room asset data.

Table 1 displays the stakeholder disciplines and their input of information into the information totems during pre- construction, construction and post-construction stages.

Table 1. PMT use of totems

	Pre-Construction	***Construction***	***Post-Construction***
Architect	*Client room number. Room name. Target briefed area.*	*Occupancy and room data sheet added in totems, linked with snagging list.*	*Asset information data. Link to O&M manuals.*
Contractor's BIM Manager	*Not applicable.*	*Site photos on a room by room basis. Snagging list.*	*Reports and links to finished room photos.*
Real Estate Department	*Mandating the information requirements of totems.*	*Finished room photos for BIM model snagging to ensure the as-built BIM model development is accurate.*	*Floor Plans. Links to O&M documentation on a central database. Asset register information.*
Lead Structural Engineer	*Not applicable.*	*Navigation between model and construction site environment.*	*Reports. Asset information data.*
Principal MEP Designer	*MEP services information. Ventilation flow rates. Room noise rating levels.*	*Room data sheet integration.*	*MEP room data. Full services documentation. Links to O&M manuals. Asset register information.*

Snagging is an expression coined in the building industry in the UK and Ireland. Snagging is defined as the process of defect identification and resolution (Sommerville and Craig, 2006). The contractor used disciplinary BIM models from the design stages to develop the project design. Design developments were uploaded in the BIM model using the federated cloud model and the updating of consecutive information totems. This federated model was used for a number of reasons, namely to: avoid clash detections; facilitate, 4D and 5D modelling; and provide a basis for the cloud BIM data base, where information totems are linked with the federated BIM. A cloud based BIM database and information totem parameters were managed by the contractor on site but was developed by the estates team. The information totems were gradually populated throughout the construction to provide a full database reflecting the changes of the as-built development. All BIM models were updated by the contractor to reflect the building completion. So called 'BIM snags' were developed to aid the development of the as-built BIM these were helped with site photographs and commentary attached to the federated model. BIM snags follow a similar function as snagging, except they are used to inform designers of any potential changes on site that need to be reflected in the as-built BIM. Laser scanned data was used to verify the validity between model and as-built building. Other documents not directly related to the BIM, such as equipment fact sheets, O&M manuals, documentation and drawings were linked into the cloud based federated model via the information totems. Currently the estates and research team are exploring ways in which Building Management Systems data (as an external source of data) will be linked via totems into the cloud based model.

7. Discussion

During the PMT focus group discussions, four main lessons emerged regarding the use of BIM and information totems during the project, namely: i) *the creation of information totems*; ii) *limitations of a semi-automatic totem*; iii) *inflexibility of software providers*; and iv) *lack of* *software integration*. First, information totems were only adopted towards the end of phase I when the Real Estate Management Team realised that FM requirements (such as building heating and cooling loads, and building usage) could have been uploaded into the BIM at the design stage to inform the design and better meet client expectations. A MEP designer said: *"Design data, such as ventilation rates, cooling loads could have been included in the design stages already, as the M &E contractors are often playing catch up from the other design team…"* Second, it was apparent that the information totems developed were not fully automated and hence, as changes to specification occurred, manual updates were needed in the model. For example, when the contractor altered a specification provided by the Architect or MEP designer (at the construction and commissioning stages). The contractor stated: *The totems still lacked automation, what would have been good was to have a live feed of the changes in the model with the totems, as they currently did not capture all of the changes in the model, some information had to be manually added to the totems…"* Third, the BIM software designers (as external providers) were unwilling to implement bespoke modifications and amendments to their software. For example, information could not be exported into other file formats for usage in room data sheets or for snagging lists post construction. A BIM Manager said: *"We were unable to export the totem information directly out of the software into a PDF, which could then be used as a room data sheet…"* Fourth, the BIM model had a distinct lack of software integration capability and therefore, when clicking on the information totem, room elevational views could not be seen and these had to be extracted from other databases within the BIM model. A Project Manager said: *"What would be useful is if we could have direct views of reflected ceiling plans, room elevations and floorplans just by clicking the totems faces, makes it easier to then share the model with subcontractors…"*

However, these aforementioned issues apart, a largely inexperienced PMT valued the input guidance and advice from the client's representative throughout the design and construction phase. This allowed the PMT to mature as a collaborative and collegiate partnership that allowed both phases of the development to be constructed and commissioned to all parties' satisfaction and with minimal disputes arising. Efficiency gains were also made by individual PMT members who acquired new knowledge of BIM that allowed them to streamline their management of the project and ultimately cut costs without adversely impacting upon quality, For example, the Architect who employed ten people during phase I, reduced this to five people in phase II. In summing up the project's success, a representative from the Contractor said: "*Phase II has been one of most successful BIM project in our business, it has really pushed BIM all the way through the process right through to FM, and we haven't actually done this on any other project to date"*.

8. Conclusion

Extant literature illustrates that BIM-FM integration presents an ideal opportunity to produce accurate design data extended throughout a building's lifecycle for retrieval during the O&M stages. This case study has revealed that an effective means of creating model infrastructure to manage data is essential at the hand over stages. By generating an information totem to add room and space related information between assets, the transition between BIM and FM is performed in an easier way for the FMT to adopt. The observations accrued from the case study have shown how an object orientated workflow can provide structure and develop complex as-built BIM models whilst embedding key O&M related information. This paper has reported upon the use of a semi-automated tool-kit promoting the use of object-orientated workflows to increase coordination, ease of communication, information exchange, ease of navigation. Future work needs to look at how information totems could be linked into existing Computerised Aided Facilities Management (CAFM) systems to be utilised at during the O&M stages. Additional development of the totems is anticipated and future research efforts will now develop a fully automated information totem.

Stimulating BIM-related supplier innovations in infrastructure projects

Anna Aminoff, Markku Niemi, Markku Kiviniemi and Pertti Lahdenperä

VTT, Finland
Anna.Aminoff@vtt.fi

Abstract

Building information modelling (BIM) is a paradigm shift in the construction industry that transforms processes to achieve greater efficiency and effectiveness. There is an increasing need for rapid development of BIM, and no organisation can do it alone, and innovation collaboration with suppliers and other external organisations is an important means to complement an organisation's knowledge base. The aim of this study is to explore how BIM-related supplier innovations can by stimulated by a public owner in infrastructure projects. Specifically, the study looks for the role of procurement in innovation. The study utilises an in-depth embedded single-case study method with 21 thematic interviews. The study applies 'innovation catalysts' identified in previous research projects as a frame of reference to identify different tactics the public owner can introduce to influence antecedents for innovation. The results of this study show that, to date, the public client's efforts to enhance BIM-related innovations has been acknowledged by suppliers. However, the results have not always been satisfactory. The results of this study suggest the probability of BIM-related supplier innovations can be increased by systematically implementing the innovation catalysts. Reciprocal, long-term, and cross-project collaboration activities are needed at different levels of the overall project organisation and within the industry, and the consistency in communication and activities needs to be ensured throughout the organisation. The incentives and requirements included in the procurement documents are suggested to be a secondary tool to promote supplier innovation, after (other) antecedents for innovations are in place.

Keywords: BIM, supplier innovations, procurement

1. Introduction

The use of building information modelling (BIM) in its current context has evolved in building construction. For the infrastructure sector the terminology has not settled; e.g. InfraBIM has been suggested. In this paper, BIM is also used to cover the processes and technologies related to modelling in the infrastructure sector. The basic benefits of modelling are mostly the same, with some differences, due to the nature of operations and business in the sector. The core features of

BIM technologies, a digital 3D representation of designed structures with computer-readable semantic data, have developed into wide utilisation varying from software development to process re-engineering or "paradigm shift" (Shelden 2009), even supporting project delivery methods like Integrated Project Delivery (IPD) (e.g. Porwal and Hewage 2013). Benefits of BIM utilisation have been evaluated in several empirical research projects (see, for example, Azhar 2011; Barlish and Sullivan 2012; Bryde et al. 2013) and reviews (Smart Market Report 2014), proving the overall influence to be positive.

No organisation can develop BIM alone, and innovation, in general, is increasingly becoming the outcome of collective effort rather than the output of a single organisation (Chesbrough and Crowther 2006). Suppliers, including designers and contractors, are natural partners to the owner to collaborate in BIM-related innovations, as the benefits of BIM are achieved only if BIM is used at every stage of a supply chain. Even though the potential of involving suppliers in the innovation process has been recognised by previous authors (Schiele 2010), empirical analysis of supply-side involvement in the focal organisation's innovation is still scarce (Luzzini et al. 2015).

To respond to this call, this study aims to answer the following research question*: How can BIM-related supplier innovations be enhanced by the public client (owner) in infrastructure projects* To research the phenomenon empirically, an embedded single-case study was conducted. We acknowledge that there are other approaches to enhance BIM-related innovations, but as the whole industry is built up in a project-based mode of delivery, this paper focuses on innovations developed as part of infrastructure projects, where the results directly support the investment project's goals. Public owners have a significant role in the development of BIM. Public owners have an interest in developing the industry as whole, and also have possibilities to develop, as they are significant players in the field due to their large number of consecutive projects. Here, we define supplier innovation as innovation developed by or with suppliers (Aminoff et al. 2015). In this study, a modern definition of innovation is used. According to this definition, in addition to traditional product or service innovations, innovations can also be related to operating practices, management methods, or processes (Kamensky 2010).

2. Literature review

As this study is positioned at the intersection of supplier innovation management, innovation in construction projects, and BIM/digitalisation in the construction sector, we briefly discuss all of these aspects here.

2.1 BIM literature

BIM research literature contains a vast number of technology development reports and case studies of implementation. The innovation aspect in the BIM literature focuses on the adoption and diffusion of BIM methods. Taylor and Levitt (2004) found that systemic innovations diffuse more slowly than comparable incremental innovations in the project-based building industry. Succar and Kassem (2015) define BIM as organisational and systemic innovation rather than solely technological solutions proliferating incrementally. They also present a comprehensive framework for BIM adoption (including implementation and diffusion at market level). Hua (2014) found that BIM diffusion is influenced by seven innovation culture dimensions, which are creativity, attitude to change, attitude to technology, attitude to learning, institutions, communication, and tolerance for dissenters; and communication was found to be the most prominent one in several phases of the diffusion. Linderoth (2010) argues that the disruptive nature of networks constituting building and construction projects creates the greatest challenge to maintaining and re-establishing the BIM network in consecutive projects. Linderoth (2010) emphasises the clients' role in demanding BIM usage and concludes another aspect: "When clients and regulative authorities start to demand use of BIM in building and construction projects, the issue of whether or not to use it is resolved". Porwal and Hewage (2013) introduce a partnering framework for public construction projects and suggest BIM adoption through BIM-partnering and the development of a collaborative BIM model for the construction process. Love et al. (2014) point out that BIM implementation is not static, and asset owners should consistently ensure that BIM benefits are materialising at the right time.

2.2 Management of supplier innovation in infrastructure projects

From an innovation perspective, the construction industry can be approached as a complex system. For each project, a large group of organisations (owners/clients, contractors, designers, material suppliers, regulators, etc.) have to collaborate as a network for the outcome. In terms of innovation, this network creates multiple sources of innovation, initiated from both the top of the project organisation (clients, regulators, professional institutions) and from the bottom of the organisation (contractors, specialist consultants, designers and component suppliers) (Davies and Harty 2013). Previous research suggests that understanding the processes by which BIM is developed, adopted, and diffused requires consideration of the networked and project-based nature of the industry (Davies and Harty 2013). Significant amounts of the industry's work are delivered in and through projects, and temporary project organisations also make up a large percentage of the overall construction organisation. Previous literature has proved that clients can enhance innovation in construction in a number of ways (Blayse and Manley 2004; Lahdenperä 2007). In Section 4, we present innovation catalysts. Innovation catalysts are a systematic way to foster innovation in construction and infrastructure projects.

As the construction sector is not unique in all respects, the literature in other industries can also be applied. Involving external partners, such as suppliers, in the innovation process has proved to be useful in many industries (Chesbrough 2003), and recent empirical studies have proved the positive overall effects on innovation of the acquisition of external knowledge (Cheng and Huizingh, 2014; Roper et al., 2013). Recent literature has increasingly treated the topic using different terminology, such as open innovation, involving suppliers in innovation or innovation alliances (Aminoff et al. 2015). If an organisation has the necessary supply management capabilities, it can integrate internal and external resources and extend innovation across organisational boundaries. Interestingly, some authors emphasise utilising the supply network, in that firms should not just focus on innovation input from individual suppliers, but firms should rather adopt a more strategic approach to utilising innovation opportunities from the supply network (Narasimhan and Narayanan 2013). In utilising its supply network, the firm must to commit to supporting innovation across the supply network (Musiolik et al. 2012), and mechanisms for two-way exchange of knowledge need to be implemented (Narasimhan and Narayanan 2013).

3. Method

A qualitative, single case-study design method was chosen to match the state of current theory and the exploratory goals of the study. A case-study design is applicable for identifying emerging themes and patterns, as it allows for acquiring rich and detailed data of the studied phenomenon (Eisenhardt 1989). Further, case research is an effective strategy in seeking to satisfy criteria of methodological rigorousness and practical relevance simultaneously (Ketokivi and Choi 2014). This study aims for theory-elaboration. It focuses on practices related to the focal organisation, and investigates several other organisations that are in relationships with the focal organisation.

The Finnish Traffic Agency (FTA) was chosen as the focal company for this study. FTA is responsible for Finland's roads, railways, and waterways. FTA is the largest client in the infrastructure sector in Finland. FTA's current spend on ongoing projects is 4.4 billion euros, and the purchases form 25% of the total infrastructure market size. FTA's strategic goal is to increase the productivity of the infrastructure sector. The products and services are not produced by FTA itself, but are procured from suppliers operating on the open markets. Given this, FTA (i) has a strong interest in developing BIM, (ii) has good possibilities to influence BIM-related innovations, (iii) and has also a high strategic incentive to develop supplier innovation. Furthermore, FTA has already developed advanced procurement processes and has applied many new procurement methods to ensure a well-functioning market and to promote the productivity of the infrastructure sector. FTA participates actively in various national and international BIM development efforts and initiatives.

We combined multiple data collection methods, with interviews being the main method. Other data sources include informal meetings, presentations, and company documents, and two workshops. In total, 21 semi-structured interviews were conducted in the study. Interviewees included 9 owner (FTA) representatives, 4 designers, 3 contractors, and 5 other experts in this topic. Interviews were conducted in autumn 2014 and spring 2015, and one interview lasted 1-1.5 hours. We selected the interviewees based on several discussions with different managers in FTA. Interviewees were selected so that they represented a good balance of different organisations and different project types where BIM has been used. However, it should be noted that BIM has been mostly used in fairly large projects so far. Interviewees that presented smaller projects had only limited real-life experience of BIM. Data collection instruments included the following topics: interviewee information, and semi-structured questions about supplier innovations, BIM in procurement, and diffusion and adaptation of best practices in the use of BIM. The instruments were slightly modified for each interviewee, based on their position. Data collection was allowed to overlap with data analysis, as recommended by Eisenhardt (1989), in the form of running commentary and field notes to identify areas of emphasis and take advantage of flexible data collection. The interview recordings were transcribed. For the purpose of analysis a conceptual coding process was conducted, to relate the information to the theory (Eisenhardt 1989).

We put a lot of effort into increasing the *validity and reliability* of the findings (Yin 2013). Semi-structured interviews help the interviewers to guide the discussion in the aimed direction, and minimise the risk of bias caused by poorly constructed interviews. The reliability was enhanced by constructing and following a case study protocol. Multiple data sources, such as informants from the FTA, designers, and contractors, as well as additional documents and reports, allowed data triangulation. This increased the construct validity of the findings in accordance with Yin (2013). The conclusions were verified in workshops with the FTA managers, to further enhance the construct validity. Furthermore, a chain of evidence was established by recording the interviews and writing field notes throughout the research process. External validity is addressed by grounding interview themes in extant research and reflecting the emerging findings with respect to previous academic understanding.

4. Framework of innovation catalysts

The study applies 'innovation catalysts' identified *in a previous research project* (Lahdenperä 2007) as a frame of reference to assess the state of the owner's activity. The catalysts were determined *as means of fostering innovation in construction and infrastructure projects*. The work was based on extensive literature by means of contents analysis (e.g. Insch et al. 1997), which offers a sound methodological frame for conducting a rigorous and systematic literature review and is also shown to be common in practice (Seuring and Gold 2012). It is important to note that the categories were formulated in the terms of the material, and therefore the approach of contents analysis was inductive (cf. Mayring 2000). The source documents of the analysis include more than 50 research and practice-oriented papers. To name a few, Winch (1998), for instance, presented a theoretical view of the management of innovation in construction as a complex systems industry, while Ling et al. (2007) compared key factors in innovation grounding in a survey of project clients. Other distinguished sources were offered by Blayse and Manley (2004) and Bossink (2004). The former identifies the main factors driving or hindering construction innovation and ends up with an itemised list of innovation strategies that are widely acknowledged as important to innovation outcomes. Correspondingly, the latter studied, distinguished, and classified various drivers of construction innovation used by construction industry actors to stimulate and facilitate innovation processes. Eventually, the work resulted in numerous principles called *innovation catalysts, pertaining to many different procedures that are considered critical in improving the preconditions for innovation in a construction project context*. They were categorised in 12 areas, presented in a compressed form below, forming the framework for subsequent evaluation.

1. **Active and competent owner**. The owner, whose competence and participation in the development and implementation of the project is important as the setter and driver of challenging and realistic demands, plays the key role in the improvement of innovation possibilities.
2. **The need and performance approach**. Communication of needs and the procurement documents of the owner, which contain performance requirements, are preconditions for

sufficient latitude in development, so that the suppliers have a genuine chance of achieving novel, improved solutions.

3. **Long-term goals**. Solutions must be sought and assessed in continuous owner projects also based on the benefit of their repeated use. Use in a single project and its economic efficiency may be the only applicable criterion.
4. **Partner selection criteria**. The selection of a supplier for a project must be based on a genuine advantage comparison, supported by carefully weighted quality and cost factors, and/or assessment of their implementation possibilities, such as being based on competence.
5. **Comprehensive network co-operation**. Innovations are born as a result of the collaboration of many parties, which means that the team of suppliers and developers taking part in the project must be involved early enough in terms of design, in addition to the owner and the main implementer.
6. **Project organisation**. Conditions for overall optimisation of services are created by procuring services as entities, where the required skills are integrated in contractual frameworks that act as a guide towards the common goal.
7. **Confidence and openness**. Open design and information systems are developed for projects, and opportunities for co-operation are supported through development workshops, common space arrangements, and systematic and faster decision-making chains.
8. **Continuous interaction during the project**. The interaction between the parties, aimed at developing the project, must start early with respect to design and continue with an emphasis on goals throughout the project, with regular evaluations of the co-operation.
9. **Continued collaboration across projects**. The goal should be to conclude comprehensive partnership agreements covering several projects, or to acquire project portfolios in collaboration, which enables deeper interaction, learning, and profitable development of solutions.
10. **Use and ownership of ideas**. Rules of the game and competitive practices are to be developed and introduced so that it is profitable for those coming up with new solutions to present them and so that the innovator gains a competitive advantage from the innovation.
11. **Risk-sharing and payment bases**. Possibilities of co-operation and development orientation are promoted by harmonising the goals of the parties so that the risk of the entity to be implemented, as well as the benefits of its success, are shared between the actors.
12. **Information and knowledge management**. Information management systems are created for processing experiential knowledge and ideas, to enable the accumulation of knowledge (in time, within an organisation) and to serve as a tool in seeking new solution proposals.

5. Results

The following sections present the findings from the empirical data. Table 1 presents the results from interviews related to each innovation catalyst, and the assessments of designers (D) and contractors (C) regarding the current status of innovation catalysts, categorised into three classes: positive (+), neutral (0), and negative (-). The numbers 1-12 refer to innovation catalysts, as presented in Section 4.

Table 1: Research data based on innovation catalyst framework (D=Designer, C=Contractor)

Catalyst	*Assessment*	*Results*
1. Active and competent owner	*D: - C: +*	*The client's forward-looking, competent, and active role in BIM development was appreciated in the interviews. The client has successfully driven BIM-related activities in the infrastructure sector, which was considered to benefit the development of the whole sector. Partly due to these efforts, the foundation for BIM exists. The suppliers follow the client's activities and aim to fulfil the client's emerging requirements.* *The client would improve BIM innovation possibilities by being more active in daily activities in the projects.*
2. The need and performance approach.	*D: - C: +*	*Defining requirements that are not too detailed, giving designers and contractors more leeway and the chance for novel solutions, was perceived as a good strategy for the future in the interviews. This approach has been trialled in some projects; however, the impact on innovation has been very modest.* *To foster innovation, the appropriate level of requirements needs to be complemented with the client's active participation in steering and feedback during project execution.*
3. Long-term goals	*D: - C: 0*	*The innovation targets, incentives, and evaluation of the results are implemented mainly on an individual project level. Based on the data, this approach is not optimal, because the main targets of a construction project typically somewhat contradict the innovation prerequisites. As an example, implementing innovations inherently increases project schedule risk. Furthermore, the project-centric approach does not very effectively support long-term development and learning, which would be important from an innovation perspectives.*
4. Partner selection criteria	*D: - C: +*	*Partner selection criteria are mostly based on company and key personnel references. This does not take innovation capabilities into account. Selection criteria suggested in the literature, namely company innovation processes, practices, and innovation statistics, have not been used.* *The quality criteria in the bidding process have little impact on the results of the process and, thus, are not seen as very attractive from a bidder's perspective.*
5. Co-operation network	*D: 0 C: 0*	*Results on this catalyst are fairly limited. However, in some pilot projects, a larger network of different stakeholders, including research institutes, has been involved. This approach has received positive feedback.*
6. Project organisation	*D: - C: 0*	*Research data indicates that the bidding process and delivery model have very significant implications for the innovation possibilities in the project. Delivery models that are based on co-operation (e.g., alliance) offer much better antecedents for innovation compared to traditional models, where contractors compete mostly on price. Notably, competition based solely on price is used quite commonly when procuring design services.* *Designer-contractor interaction is one important element that can stimulate innovation. The chosen delivery model obviously has a major influence on the interaction. Therefore, acquiring design services and contractors separately is not always the best model from an innovation standpoint.*
7. Confidence and openness	*D: - C: 0*	*The alliance model has enabled an open, innovation-friendly atmosphere and changed decision-making in the projects. The PPP-model and Design-Build have been significantly worse in this respect.* *Pre-project development workshops for the client and bidders have increased the possibility for interaction, and received positive feedback in the interviews. This method has also yielded positive concrete results in the projects.*

8. Continuous interaction during project	*D: - C: 0*	*A two-phase bidding process has increased innovation. However, this method also has some negative effects, as companies that have lost the bidding process have considered the financial compensation from their innovations inadequate.* *The client is implementing a consistent project feedback system that is expected to improve innovation prerequisites and feedback mechanisms.*
9. Continued collaboratio n across projects	*D: 0 C: 0*	*The data indicates that, currently, co-operation over several projects is quite rare. However, the literature suggests that collaboration over a long time and over several projects increases innovation probability significantly, because it enables the use of a learning curve.* *This catalyst clearly has under-utilised potential in the client organisation. Public legislation might set some restrictions in this regard.*
10. Use and ownership of ideas	*D: 0 C: -*	*Some practices used with respect to innovation ownership are not always considered fair. This can be a very significant innovation barrier and should therefore be carefully considered by the client.*
11. Risk-sharing and payment bases	*D: - C: -*	*Data indicates that the risks of implementing innovations in projects are currently primarily on designers and contractors. These innovation risks are amplified by the fact that implementing innovation in the projects inherently adds schedule and financial uncertainties. Significant financial sanctions are often tied to the project's main targets (e.g., schedule and budget). A different risk balance between the client, designers, and contractors is expected to increase interest in the innovation activities.*
12. Knowledge management	*D: 0 C: -*	*The client is actively following the business innovation and research activities in the sector, including R&D investments and the number of patents. Starting to follow these parameters on an individual company level and using this company-level data in the bidding processes would be a strong indicator from the client on the importance of innovation.*

The results indicate that the client has actively implemented some innovation catalyst principles. Some other catalysts have been experimented with in a few projects, but are not used systematically throughout the project portfolio. The third group consists of catalyst practices that have not been used at all. The results suggest that using catalysts as a frame of reference offers a systematic method to analyse innovation practices in the projects. To further improve the possibilities for innovation, the client should focus more on the catalysts that have not been actively used so far. Specifically, efforts should be strengthened in the areas that have been used occasionally, and that have given positive results.

Generally, designers consider their possibilities for BIM-related innovation fairly weak, and were quite critical of the possibilities to develop innovations in the projects. This is somewhat alarming, as designers are in a pivotal role in developing BIM further. Designers naturally play a key role in the first phases of a project, and therefore they create the foundation for the BIM usage during the project lifetime. The possibilities for BIM-related innovations in the later phases of the project are significantly weaker if BIM potential is not fully realised from the start of the project. Currently, modelling means mostly additional work for designers, and this additional workload is not fully taken into account in the designer's fees. A major portion of the BIM benefits are capitalised in the later phases of the project. Contractors, on the other hand, were fairly positive about BIM-related innovations. Based on the research data, contractors seem to have the best overall view of the infrastructure project and the role that modelling can play in it. Contractors also get the most significant financial benefit from modelling. In particular, BIM-enabled automatic machine control increases contractor efficiency and enables cost savings.

The findings from our data emphasise the role of the project delivery model in creating antecedents for innovation, and the alliance model seems to offer much better antecedents for innovation compared to traditional models, where contractors compete mostly on price. Our results also emphasise the importance of consistency in the client's behaviour and communication, as the suppliers are eager to support the strategies of the client.

6. Discussion

The findings of this study contribute to the literature by describing how a public client organisation can stimulate BIM-related innovation. As the infrastructure sector operates in a project-based mode of delivery, it is critical to understand how innovation can be stimulated in the projects. In the literature, BIM innovation is referenced as a somehow monolithic concept, although it is a wide set of methods, technologies, and processes. Each of these should be managed in order to achieve further development. BIM innovation is decentralised and should be implemented in cooperation with suppliers. Innovation in infrastructure projects, driven by clients, designers, and contractors, mainly focuses on added value, cost savings, or productivity, and BIM innovations are seen as enablers for those. In the interviews in this study, the interviewees often discussed innovation in general, and in some interviews it was difficult to guide the discussion back to BIM-related innovation. However, our results suggest that enhancing the antecedents for innovation in general also stimulates BIM-related innovation.

In this study, we utilised a framework of innovation catalysts, which is based on an extensive literature review conducted in a previous project, to assess the empirical research data. Based on the innovation catalysts, there is a multitude of different factors that influence the possibilities for innovation. A client can actively manage these factors. It is important to ensure that the antecedents for innovation are in place in the projects that aim for BIM-related innovations. Our results emphasise the role of procurement in innovation, as many of the identified methods that improve the antecedents of innovation require the use of advanced procurement strategies. Thus, this study also brings a further aspect to the purchasing literature, which discusses the involvement of procurement in supplier innovation (Johnsen 2009; Luzzini et al. 2015). Secondly, we observed that the perceptions of designers and contractors differ significantly, and this might prevent innovation goals from being reached. The main reason for this is that designers see that they do not get enough benefits from using BIM, and see it mainly as extra work. This is supported by the previous literature on inter-organisational innovation, which emphasises the importance of benefitting from innovation (Luzzini et al. 2015). The previous literature has also discussed the importance of congruencies in perceptions in achieving relationship targets (Aminoff and Tanskanen 2013). Thus, the client should focus on making sure that designers also get, and understand, the benefits of using BIM, either in the short term or the long term. There is some evidence (Barlish and Sullivan 2012) that the total costs of construction project have been lower than expected, even though the design costs have been higher due to BIM-based design.

Our study extends – in the context of BIM innovation – the previous authors' proposition (Tawiah and Russell 2008; Lloyd-Walker et al. 2014; Lahdenperä 2007) that the delivery model influences the probability for innovation in general, with the alliance model offering the best antecedents. In theory, the PPP project model also opens up wider innovation possibilities, as the whole life-cycle of the construct, including operation and maintenance phases, is open for innovation. However, based on the data, PPP models have not led to good results from the viewpoint of innovation. In PPP models, the tight schedule and financial constraints are dominating criteria, and this leaves very few possibilities to take risks during the project. Risk inherently goes hand-in-hand with innovation. Our results also indicate that extensive PPP tender processes that are implemented in multiple phases create a difficult situation for bidders. They need to consider how much information to put into the tender response without revealing critical information to their competitors. Our results also emphasise the importance of consistency in the client's behaviour and communication, as the suppliers are eager to support the strategies of the client. This is a common challenge in supplier innovation management (Luzzini et al. 2015), as there are different interests and objectives in different parts of organisations. Consistency is at risk, specifically, when the owner involves a separate construction management consultant to manage the project. Thus, by putting effort into systematic project-level influencing tactics, the client could enhance development and innovation activities. Moreover, in the project-based industry, the diffusion of innovation into consecutive projects has been seen as problematic (Taylor and Levitt 2004; Linderoth 2010). It is obvious that the long-term asset owner should have the motivation and competence to support this kind of BIM implementation across projects. The results of this study also propose that one project is too short a time to assess innovation, and looking for innovation across projects might yield better innovation results in the context of BIM innovation.

This study presents initial but promising results on stimulating BIM-related innovation in infrastructure projects. The empirical context was, however, limited to a single case study, and thus the results need to be verified with further case studies. Second, it would be interesting to study how BIM-related innovation can be developed using approaches other than as part of an infrastructure project, for instance using innovation procurement models, such as the pre-commercial procurement model (PCP model).

7. Conclusions

Building information modelling (BIM) is a paradigm shift in the construction industry. BIM transforms and digitalises processes, and therefore increases efficiency and effectiveness. Importantly, BIM innovation is an enabler for more comprehensive digitalisation of the construction process. Because BIM influences many aspects of the construction process, BIM development and innovation requires a joint effort and good co-operation between many parties. This requires careful consideration, but can be very powerful when implemented successfully. This study investigates how BIM-related supplier innovation can be stimulated by the owner of infrastructure projects. Our results highlights that a public sector owner can stimulate supplier innovation by actively increasing the antecedents of innovation. We identify several tactics that a client can use to stimulate BIM-related innovation and, thus, to manage supplier innovation. Reciprocal, long-term, and cross-project collaboration activities are needed at different levels of the organisation. The traditional way of managing infrastructure projects by sanctions does not optimally support innovation. Furthermore, based on the study, using economic incentives for innovation is not sufficient in many cases, as other project priorities might be in contradiction with the innovation targets. Innovation catalysts offer a systematic framework for the client organisation to assess the possibilities and preconditions for innovation in any given project. The results propose that the selection of delivery method strongly influences the antecedents for innovation – with the alliance model supporting innovation best.

Abstract

This paper reports and discusses the status in a Norwegian research-based innovation project called ”SamBIM – BIM-driven collaboration in the building process”. The overall aim of SamBIM is to develop BIM-driven processes and collaborative models that boost value creation in construction projects, the AEC-industry and in the SamBIM-companies. SamBIM is funded by the Norwegian Research Council. The project partners are leading and R&D active companies in the Norwegian AEC-industry, representing various parts of the building process value-chain. SamBIM focuses in particular on the interface between programming, design, and the production phase. Important characteristics of the project is the holistic and interdisciplinary approach to phenomena studied in five ambitious real-life projects, the action research inspired methodology, and the use of change-agents as the "innovation gear" between research and practice. The SamBIM project concludes in 2016.

In this paper, we present preliminary results of the case studies. We furthermore investigate different foci, implementation angles, practice, and development of BIM-driven collaboration, both in the individual case project and in the SamBIM project in general. The paper discusses possibilities and challenges related to the research design and methodological approach of the innovation project. Knowledge development and learning across maturity levels, formal and informal implementation strategies, collaboration across scales (multidisciplinary dimensions, life-cycle perspectives), process models for collaboration, and measures to obtain high quality BIM-driven collaboration in the building process are among the subjects appraised. The multidisciplinary profile of the research team has been fruitful in order to grasp the complexity of the observed phenomena. The broad approach has made it possible to view SamBIM topics from different traditions, both practically and theoretically. The research has contributed to increase the industry partner's knowledge, as it has contributed to the scholarly literature (particularly through the two embedded Ph.d-studies).

Keywords: BIM, Building process, Collaboration, Case study, Implementation.

1. Introduction

In this explorative paper, we present and discuss the first lessons learned in a Norwegian ongoing research-based innovation project called "SamBIM – BIM-driven collaboration in the building process" (2012-2016). We address two main questions:

- How can we identify main drivers for successful BIM-driven collaboration?
- How can in-depth case studies of the building process in real-life projects reveal such drivers?

Implementing new technology alone does not necessarily improve the way we work and interact in building projects. Improvement seems to require an understanding of the interrelationship between technological, processual and people-related factors (Moum 2008, Owen et al. 2010). To manage and implement change and innovation processes is epically challenging in the AEC-industry (Architecture, Engineering, and Construction). The industry has some particular characteristics (Dubois and Gadde 2002, Eccles 1981), making innovations challenging to deploy (Harty 2005). Harty (2005) points out five factors central to understand how innovations are deployed in the AEC-industry: 1) Tasks are often conducted as collaboration between several firms, with own resources, practices and goals. 2) The work is project-based, and there are often large numbers of people and companies involved. 3) The work is dependent on information sharing across organizations. 4) The tasks intersect organizational boundaries. 5) Each involved firm influences on the project by own practices and expectations.

Inter-organizational collaboration, complex interdependencies, and the absence of a single actor who can ensure a unitary implementation and use of BIM for the whole project characterize the context of the SamBIM-project. In the following, we describe the SamBIM scope, objectives and the methodological approach. We furthermore present the case studies and some first tentative findings, before we explore on the two questions above. We wrap up the paper with some concluding remarks.

2. SamBIM's scope and objectives

The successful collaboration and interaction between the people involved in the programming, design and production of building projects is a key to value-creation. This has traditionally been a challenging quest in temporary and non-continuous project teams. Such teams are typically comprised of companies who have never worked together before, who are representing different roles, interests and disciplines, and who are responsible for different parts of the process. The implementation and use of BIM (Building Information Modelling) is expected to improve collaboration and enable new and more efficient ways of working. Around fifteen years ago, the first companies in the Norwegian AEC-industry started implementing and using various BIM-tools. The implementation of the first generation of BIM demonstrated positive effects on design team coordination. Still, the industry is yet not enhancing the full potential of BIM beyond the goals and achievements of individual participants and phases. An initial state-of-the art review in SamBIM identified a need for more holistic knowledge on BIM-driven cooperation across phases and actors. SamBIMs multidisciplinary approach relates to architecture, technology and construction management as well as organizational studies and sociology.

The overall aim of SamBIM is to develop BIM-driven processes and collaborative models that boost value creation in the SamBIM partners, in the building projects, and in the AEC-industry. This is to be obtained by processes that are more efficient, customized end-products, better use of resources, reduced costs, less process-related building defects, and less waste. In SamBIM, leading Norwegian AEC-companies and research environments are together identifying and developing knowledge. Experiences are gained from exploring collaborative models and processes in real-life building projects with high BIM-ambitions. The partners expect research outcomes and innovations with positive impact on the planning and production of buildings, such as:

- Successful adaption of new working methods, for instance Lean Construction principles, ICE (integrated concurrent engineering) and more;
- Improved competence of the client, consultants and contractors when it comes to purchasing and supplying services in BIM-supported building projects;
- Improved information flow and coordination – with particular focus on the interface between programming (client requirements), design and production of building projects
- Better understanding of roles, responsibility and tasks – and of management and organizational drivers and barriers in BIM-ambitious building projects.
- Less errors and better buildings.

3. Methodological approach

SamBIM is an Innovation Project for the Industrial Sector funded by User-driven Research based Innovation (BIA), a programme of The Research Council of Norway (RCN). The BIA programme aims to promote value creation in Norwegian trade and industry through research-based innovation in companies and the R&D environments with which they cooperate (RCN 2015). Innovation Projects are owned by a company or an organization. They include research activities and knowledge development needed for implementing innovations and value-creating renewals. These projects call for a research methodology enabling a high degree of interaction between the industrial partners and the involved R&D environments. A successful implementation enabling a subsequent value-creating effect in the companies is crucial.

The SamBIM methodology addresses the premises of RCN in several ways (Fig.1). Firstly, action-research inspired case studies of real-life building projects serve as an arena for both data collection and interactive knowledge development. Important criteria for selecting the real life projects were: 1) High ambitions of BIM-use and collaboration, and 2) Participation of a SamBIM company in the project. The research group has carried out open-ended and semi-structured interviews (individuals and groups) at different levels in the companies: at strategic level (management, client), tactical level (project management), and operative level (architects, consultants, BIM advisers). The group has furthermore observed project meetings and other project process related activities as well as relevant documents. The questions are targeting processes, people involved, technologies used, and the interrelationship between these. This

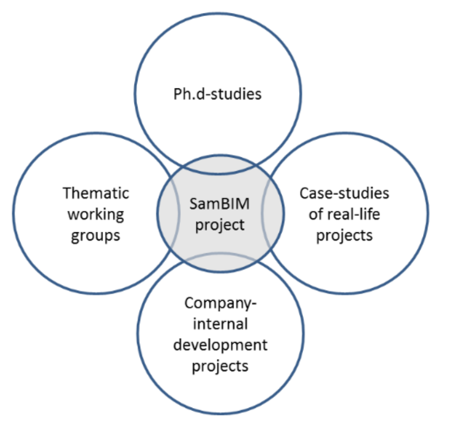

Figure 1: SamBIM as a learning hub

paper primarily presents findings from these case studies. Secondly, based on the data from the first case studies, thematic working groups were established to elaborate on cross-case challenges. Thirdly, the industry partners have kicked off company-internal development projects. Fourth, Ph.D-students are digging deeply into core issues of SamBIM. SamBIM is a learning hub, interconnecting and boosting knowledge development and implementation across the arenas in Figure 1. An important measure for ensuring a close interaction between the different learning arenas, and between the industry- and research partners, has been the so called "change agents". Each of the companies involved have appointed an employee to this role. The change agents support SamBIM as "innovation-gears" and gate-openers, acting as two-way contact points between research and practice. They assist the research activities by driving necessary internal coordination, mobilisation, and information work in their companies. They are giving access to case studies, driving forward some of the thematic working groups, and they are active participants in workshops and SamBIM project meetings.

4. SamBIM as a learning hub

4.1 The SamBIM consortium

The project owner of SamBIM is Skanska Norway, one of the biggest contractors in Norway. Skanska's industry partners are Statsbygg (building commissioner), Multiconsult (an interdisciplinary consultant company) and LINK Architecture. All of them are R&D active and linked to international sister companies or equivalent organizations in other countries. They are front-runners in BIM implementation, and are involved in networks and joint initiatives such as BuildingSMART, Lean Construction Norway and more. Together these companies represent the stages of the building process crucial to SamBIM: programming, design and production. The industry partners have committed a multidisciplinary research group as required by the complex and broad objectives of SamBIM. The R&D partners are SINTEF Building and Infrastructure, Fafo, and The Norwegian University of Science and Technology (NTNU). Around five researchers and two Ph.D-students are involved in the project on a continuous basis, with expertise from architectural and engineering sciences, technology implementation, process-related research and social sciences.

4.2 Thematic focus areas

Both researchers and industry partners contribute in the thematic working groups, established by the need to dig deeper into specific topics:

- *Barriers and drivers for collaboration*; aims to identify barriers and drivers for co-location/integrated concurrent engineering in the design phase of constructions projects, opportunities and obstacles for mutual adaptation of technology, and organization and process among actors in the design phase. *Ambition:* to publish a publicly available *collaboration guide*.
- *Lean Construction;* aims to facilitate arenas where topics related to Lean Construction are discussed and further developed, and to obtain a more unambiguously perceived term, both by researchers and industry partners. *Ambition:* to collaborate with the Lean Construction Norway network to spread the results of the SamBIM project.
- *A common process model;* aims to develop a common process model for the building process, from cradle to grave. The SamBIM findings have been communicated to a national initiative on a new norm for describing the stages of a building process, inspired by the RIBAs plan of work in the UK.

4.3 The case studies – tentative findings

The SamBIM-team has carried out five case studies of real-life building projects (Table 1). Two of them are still ongoing (spring 2016). This section briefly presents tentative findings from each of these case studies.

Table 1: Overview of the SamBIM case studies.

4.3.1 Risløkka

The case deals with the refurbishment of a medium-sized office building located in Oslo, for the Public Roads Administration. Statsbygg acted as building commissioner. Already in the pre-design phase, Statsbygg appointed this project to become a SamBIM case study. Because of the connection to SamBIM, Statsbygg and the design team agreed on testing out the following Lean Construction-inspired work principles in the design phase:

- Co-location of the design team and Statsbygg twice a week;
- Working principles inspired by *Integrated concurrent engineering;*
- The use of a so-called planning matrix and *action items.*

Bråthen et al. (2014) and Bråthen and Moum (2015a) identify driving and restraining forces affecting the BIM implementation in this case study. Rather than just studying its effects, the actual implementation was also in focus. The analysis displays that a successful implementation of BIM largely depends upon a participative and co-operative process at the ground level. At this, the significant project participants must be involved in the development of a BIM-implementation-plan. This plan should reflect interests and goals of the involved parties. The analysis points out that related discussions and negotiations can ensure ownership and the design team participants' commitment to an innovative and, for some, unfamiliar BIM-process. The study also shows that working principles based on Lean Construction contributed to a more dynamic design team. Especially the combination of BIM and co-location opened up for working in a new and more efficient way. When working co-located the designers used BIM to show each other possible solutions and problems and could make clarifications and decisions “there and then”. According to our informants this implied faster decisions and better interdisciplinary working compared to a “traditional design process” (Bråthen et al. 2014). However, such a way of working requires that all participants are present and have decision-making authority.

4.3.2 Veitvet

The Veitvet primary and lower secondary school was a public-private partnership project (PPP), partnering the turnkey contractor and property developer Skanska and the municipality of Oslo. It was a Future-build and BREEAM Very Good project, with high environmental ambitions (passive-house level). It seemed that the project had a high potential for innovation and collaboration between the professional participants of the building process. The SamBIM partner LINK Architecture had a role as responsible architect. Initially, the BIM ambitions were high, and the ambitions from the research project SamBIM should be implemented in the Veitvet project. Due to different circumstances, the project was however withdrawn as a case quite early in the SamBIM project.

The findings reveal that the project in practice seemed to develop into a traditional turnkey project, and that the formalized BIM requirements neither were met nor implemented. The collaboration seems to have failed, partly due to challenges concerning the PPP model and contractual structures between the "partnering" participants (fixed prices), and partly because the model for collaboration was not sufficiently developed and/or rooted in the contractors' management. Both BIM model and paper drawings were requested by the project management, which may have resulted in an unclear perception of the model for project management and collaboration (as a mix of traditional management and BIM) (Flyen 2016a). Even if Veitvet was terminated as a SamBIM case project, the experiences had major ripple effects and seem to have made a vast contribution to the later development of a Skanska process model for collaboration used in subsequent projects.

4.3.3 Deichmanske

In 2013, Oslo Agency for Cultural Affairs commissioned a new library building. The new main branch of Deichman, Oslo's public library, is currently under construction in Bjørvika. The SamBIM partner Multiconsult won the main engineering contract for the new library, including the responsibility for coordinating the design team. Together with three other consultant companies, they are responsible for the detailed design phase. Multiconsult has for several years been developing a generic process model for BIM-enabled projects. As a part of the Deichman project, Multiconsult wanted to streamline and improve their model further, through experiences and insight from this significant project. Related to this aspiration, SamBIM's research partners have mainly focused on the following topic in this case:

- Effects of connecting BIM to the process model through milestones. This implies that decisions about the model status in different zones of the building will be frozen at a certain date.

Skinnarland (2015) found that using a Multiconsult process model has been a valuable experience for the various actors in the design team. Using the model puts pressure on the actors to make decisions in accordance with the model, often on an earlier point of time in the process than they normally do. The informants considered the model to have contributed to more and better interdisciplinary collaboration within the design team. However, Skinnarland (2015) found a mismatch between Multiconsult's position within the design team and their possibility to put pressure on the other companies to make all their decisions in accordance with the model. Consequently, one important conclusion from the case study is that too little attention was devoted by Multiconsult on core elements in the implementation and development process of the process model. The model was introduced to all participants in the design team without sufficient discussion. Hence, a necessary ownership was not created, nor a common vision for the use of the process model. These shortcomings were probably significant for the less successful results compared to what was expected when using the model in the detailed design phase.

4.3.4 Urbygningen

The case deals with the refurbishment of a University building named Urbygningen at the Norwegian University of Life Sciences located outside Oslo, with Statsbygg as the building commissioner. The preliminary design completed in 2009. In 2013, Statsbygg initialized the detailed design phase. The ongoing construction phase started in august 2014. The design team consists of several Norwegian, Oslo-based companies. The SamBIM partner Skanska was chosen as the general contractor. Statsbygg wanted to test the following in the design and construction phase, respectively:

- BIM combined with co-location of the design team, methods inspired by lean design methods;
- BIM for site workers in the construction phase ("BIM kiosks").

Statsbygg's expectation was that BIM and the lean-design-inspired work principles would lead to better collaboration among the involved actors, and thus lead to an improved design process.

The data suggest that this principally occurred. The findings indicate that BIM combined with some of the lean work principles yielded good results regarding the intentions, through linking the team stronger together, technologically as well as organizationally. In particular, it turned out that the combination of BIM and co-location of the design team created good results. The findings indicate that this approach helped to improve the inter-organizational and interdisciplinary collaboration. It fostered faster communication and made improvements in latency, as well as contributing to a better social climate in the design team. However, the data also suggest that not all parts of the contractual "BIM and Lean-package" were equally successful in practice. The analysis indicates that the various pieces of the lean and BIM concept were emphasized differently in the implementation process. Elements given little or no attention in the implementation process are less likely to lead to good results. In the construction phase, Statsbygg and Skanska introduced so-called «BIM computer-kiosks» in order to allow site workers on-site access to 3D models. Bråthen and Moum (2015b) investigated the use of the computer kiosks and the related consequences. The findings indicate that there are great advantages by adopting BIM and similar technology at the construction site. This relates, among others, to the fact that the workers obtain a more holistic understanding of the planned building through the excellent possibilities for visualization. The workers get the ability to investigate particularly complex issues and to access details that hardly can be seen on a traditional paper drawing. In addition, the findings indicate that in certain cases the data kiosks facilitate a greater level of face-to-face collaboration between site workers. This occurs because workers meet, both planned and randomly, to discuss in front of the computer kiosk while using the model for visualizing complex issues. This means that the data kiosks can pave the way for new on-site collaboration forms.

4.3.5 Eikefjord

The Eikefjord primary and lower secondary school case is a comprehensive demolition- and new building project situated on the coast of Western Norway. The project- and building owner is Flora municipality. The execution model is interaction based turnkey contracting. The SamBIM partner Skanska is the Turnkey contractor (engineering, procurement and construction). The researchers from the SamBIM project have been following the project from the initiation of the design-build and tendering competition, through the design process and start-up of construction works. Eikefjord is the fifth and final case-project in SamBIM. The process encompassed demolition, relocation and temporary housing of school functions, building of the new school and sports arena, and build-up of outdoor areas. The school operations were to be running parallel to the demolition of the old school and building of the new, with operations partly in the localities of the old school, temporary barracks, and gradually employing the new buildings. Skanska generated an internally developed collaboration process model prior to the initiation of the early stages in the design-build tendering competition. The case project was a pilot for the new process model. The project team was complete already from the initial stages of the competition, adapting full collaboration, team building, and collective experience learning from early design and composition of tender. Skanska managed the project and the project design team, had the BIM coordinator and a process supervisor/change agent to follow collaboration process. Consultants, architects, and manufacturers were both locally- and

Oslo based. Both collaboration- and BIM ambitions were initially high, and the research focused on the following areas in the collaboration process model employed in the case project:

- Implementation of a collaborative focus from initialization of design-build and tendering competition;
- Lean-construction inspired backwards planning/scheduling and implementation of tendering, design and construction stages;
- High BIM-ambitions, both in tendering, design, and construction, and as a support tool for close collaboration;
- Workshop-based collaboration approach, with frequent gatherings;
- Virtual and physical BIG-ROOMs in the design phase.

The primary focus of the newly developed process model ensured collaboration and co-localization from initial start-up, and upheld the baseline goals agreed upon throughout the whole of the process. Due to the partners' different localities, a continuous focus on collaboration has been imperative. The use of virtual and physical BIG-ROOMs, frequent workshops, and clarification of expectations for deliverables for each other to the next gathering has been important drivers to achieve this goal. The Lean construction-inspired scheduling approach yielded complete overview of all participants and interfaces. Both holistic and interface coverage between professions has successfully been ensured by the all-team and two-party clarification meetings during the workshops. The consensus-based rules for collaboration and workshop-based process ensured a rapid and effective design process, but required that all participants were present and had decision-making authority in the workshops (also the owner). The results of the earlier case projects in SamBIM seems to have inspired, and partly driven, the development of the Skanska collaboration model. The experiences with the model so far are very promising in terms of efficiency and quality of both collaboration and project results (Flyen 2016b). The model has thus proven to be an important driver for collaboration and the use of BIM in construction projects. Further, the participants have expressed that this way of collaboration is inspiring and positive, and that they want to continue to pursue this approach in further projects.

5. Discussion - Learning from SamBIM

What are the first lessons learned across the single case studies and adjacent activities? In the following, we discuss how the SamBIM team has identified main drivers for successful BIM-driven collaboration. We elaborate on three key topics: 1) learning loops and maturity levels 2) implementation strategies and, 3) commitment and continuity.

5.1 Learning loops and maturity levels

Three factors were particularly challenging throughout the project: 1) to achieve a shared understanding of ambitions, activities and roles, 2) to find appropriate case studies and, 3) to close the gap between the ambitions and the various maturity levels in the organizations and the projects. The initial ambitions of SamBIM were high. The starting point was a broad and holistic view on developing new ways of collaboration, enhancing the full potential of BIM. The partners wanted to develop new generic models and methods, which, in the next step, should be applicable for other actors in the Norwegian AEC-industry. To orientate in this rather complex landscape of interdependencies, and to operationalize the overall objectives into definite actions, required much effort in the first stage of SamBIM. The related discussions between the researchers and the practitioners (and the study of state-of-the-art elsewhere/in the industry) gave valuable guidance. Based on the knowledge gained from the case studies and the discussions about the goals and ambitions, the SamBIM-team decided to establish three thematic working groups as an arena for elaborating the selected cross-case topics as previously described. An important function of this work is to transform the pool of empirical data into definite and applicable outcomes for the industry partners. Important topics in the SamBIM-team discussions were e.g.; to which degree can the SamBIM project realistically hope to influence on cultures of collaboration within real-life projects and organizations? What is process-innovation for each of the partners involved?

Finding real-life projects to match the high ambitions of investigating new ways of collaboration and advanced BIM-use from early design to production was challenging in the first stage of the SamBIM-project. The partners had thus to apply a rather pragmatic approach to narrowing down the scope and limiting the ambitions. It was necessary to adjust to the restraints of the available case studies, and to the maturity of the involved organizations. Still, as the project developed and the insight and the maturity of the industry partners increased, new cases replaced or succeeded the initial ones. The new projects could thus benefit from the preceding experiences. An example is Skanska's steep learning curve on their way from the Veitvet to the Eikefjord case.

Would SamBIM have benefited from a more limited scope and more mature case studies from the beginning? Not necessarily. To move from the overall picture down to the details, and to research the not-perfect real-life situations might have been challenging, time-consuming and partly painful. This process has however also revealed findings and experiences, which might otherwise have remained undiscovered. More important, this process has been useful in order to harmonize the progress with the actors' need for time to move upwards on the learning ladder, step by step.

5.2 Formal and informal implementation

The case studies show, in different ways, the importance of a good understanding of implementation drivers and related strategies. An obvious implementation driver for "SamBIM-working" (BIM-driven collaboration) is formal contractual requirements of the client (for instance early contractor involvement and co-location/big-room solutions). The SamBIM findings do however indicate that this is not enough to achieve successful implementation and related change of traditional practice. Not only formal, but also informal drivers of implementation can be powerful. For instance a dedicated design manager (or a change agent), who, with a personal engagement and belief in what he/she is doing, motivates and inspires colleagues or a team to try out new technologies or ways of working. A good implementation strategy should include formal measures, as it should take into account, be aware of, and utilize the power of informal drivers such as involvement and participation of involved parties.

5.3 Commitment and continuity

Initially, one of the case-study criteria was that at least one SamBIM industry partner had to be involved in the building case projects. The role (and the authority) of the partner in the project affects the ambitions and possibilities of a broad implementation. Statsbygg and Skanska in their client or turnkey contractor role could put pressure on the implementation of the SamBIM-approach (top-down). The architect or the consultant company (bottom-up) did not have the same impact in the projects with an external and not "SamBIM-committed" client. To create interest and commitment among all building project participants, would enable a broader impact and probably also enhance greater benefits. This is however not always possible, and calls for activities with realistic scope, adjusted to the constraints of what is possible to test or change. Tight collaboration between research partners and industry partners is an important premise for success in innovation projects such as SamBIM. In AEC-companies, there is often a high labor turnover and change of people in management positions. The SamBIM-companies have been no exception to this. Throughout the project period, the team members in the SamBIM group have changed several times, including the project management. This creates challenges for the team building and the continuity of the work. The same situation has also partly characterized the building projects studied. Changes in work force can affect both positively and negatively on the progress and success of a project. They are however unpredictable and not possible to influence on. This makes it even more important to create robustness in organizing such tight research-practice collaborations.

6. Concluding remarks

A motivation and crucial expectation of the industry partners (and the Norwegian Research Council) is that the SamBIM-activities will contribute to actual improvement of their practice. This is relevant both for the building projects they are involved in, and for their own organizations. In order to wrap up this tentative report, we summarize how in-depth case-studies of the building process in real-life projects has revealed main drivers for successful BIM-driven collaboration:

- Learning across the case-studies has been highly valuable. To develop knowledge step-by-step from case to case has given an added value to the SamBIM project beyond what would have been possible with parallel and isolated cases;
- To develop and implement research-based knowledge on holistic, “soft” and hard-to-measure issues in real life settings is challenging. In SamBIM, it has been important to allow for maturation, unexpected findings, necessary corrections and limitations as the insight and understanding among the partners have gradually grown;
- The dynamic interchange between the four knowledge development arenas (Figure 1) has been highly valuable. The activities have boosted each other and the progress of the SamBIM project. They have also stimulated learning loops and continuously pushed the partners into investing in new fields;
- The multidisciplinary profile of the research team has been fruitful in order to grasp the complexity of the observed phenomena. The broad approach has made it possible to view the SamBIM topics from different traditions, both practically and theoretically. The research has contributed to increase the industry partner's knowledge, as well as to the scholarly literature (the latter particularly through the Ph.d-works);

- The close interaction between the researchers and the industry partners has been a driver in SamBIM, with the dedicated change agents in front;
- The complexity of both the consortium and the research requires clarified roles and responsibilities, and a common understanding of aims and ambitions;
- In SamBIM, it has become important to both strive for the high and ambitious goals (long runs), and grasp for the low-hanging fruits (short runs). The Urbygningen BIM-kiosk or the big-room of Risløkka enhanced an immediate effect which was useful and motivating, and which created pride and ownership among the actors involved.

The SamBIM project will be completed in the autumn of 2016. Important work to be done in the last stage of the project are the cross-case and cross-activity analyses and summaries, the deliveries of the thematic working groups, and the dissemination of the findings from the project in its totality.

Acknowledgement

We gratefully acknowledge the collaboration with and contributions from the partners in SamBIM:

- Industry partners: Skanska Norway (project owner), Statsbygg (The Norwegian government's key advisor in construction and property affairs, building comissioner, property manager and property developer), Multiconsult and LINK Architecture;
- Interdisciplinary research group; SINTEF Building and Infrastructure, Fafo and NTNU (The Norwegian University of Science and Technology).

The Implications of BIM Use on Communication Channels in the Design Process

Aljwhara Alnaser and Chris Harty

University of Reading, UK
Email: a.a.a.alnaser@pgr.reading.ac.uk

Abstract

This research aims to explore the implications of building information modelling (BIM) implementation for existing communication channels used in design processes across various professionals in the Kingdom of Saudi Arabia. Although there is much research on communication channels in terms of their effectiveness, related to collaborative environments such as face to face meetings vs. computer-mediated communication (CMC), there is relatively little research known about the consequences of implementing BIM on the existing mechanisms used for communication within firms. In doing this research, three different sets of concepts have been mobilised with the aim of understanding the dynamic processes of communication across diverse professionals in general and within BIM collaborative environments in particular. These concepts are theoretical models of the communication process (from linear to interaction processes); team theory, and cross professions collaboration theory. These were reviewed to identify 38 distinct factors, selected in relation to how relevant they are to potential changes in communication channels. The factors are grouped into three major themes; collaborative team characteristics, leadership and methodology of information exchange. These are then used to develop a framework to examine the implications and effects of BIM on communication channels. Empirically, a pilot case study strategy is employed, with data collected from four medium-large firms in KSA through semi-structure interviews and a questionnaire. The initial findings of the case-study reveal that the changes in communication channels experienced through using BIM differed depending on several factors. Although many factors were common across the three sets of literature, their influences empirically were diverse. Factors such as resistance by professionals to change to new or alternative communication channels not only referred to the lack of training or education but also, to a 'familiarity' factor. Furthermore, there is an influence of 'spreading rumour' (pre-existing assumptions and expectations) on adoption of communication channels which appeared more at the decision maker level.

Keywords: Communication channels, BIM, Professionals, Influential factors, KSA Firms

1. Introduction

There is an ongoing debate about what BIM is. A number of definitions from professionals and researchers alike have described the BIM philosophy in different ways. For some, BIM is *'data sharing, and not only data exchange'* (Nour 2012: 1), for others it is an integrated model (Sebastian 2011), or it is *'a software application'* (Aranda-Mena et al. 2009: 420), or shared digital representations, and language allowing interoperability (McGraw-Hill 2008). As the perceived definitions differ, this leads in turn to enquire about how design representations are exchanged across BIM communication channels. This research aims to explore the implications of building information modelling (BIM) implementation for existing communication channels used in design processes across various professionals in the Kingdom of Saudi Arabia. The paper is structured as follows; first, relevant literature on communications, teams and collaboration are used to describe the extraction of factors which may influence communication channels in BIM projects, following this, the iterative research approach for this pilot study is discussed. The analysis is then presented under main themes of team characteristics, leadership, and information exchange processes, before the main findings and conclusions are described.

One of the core features of BIM is 'interoperability' (Succar 2009), defined by IEEE (1990: 114), as *"the ability of two or more systems or components to exchange information and to use the information that has been exchanged".* This process of exchange and sharing of information reflects two pillars of BIM work; communication and collaboration (Azhar et al. 2012). Referring to the findings in the literature, in relation to the role of the collaborative team, there is a consensus about team work is a third pillar. Reviewing the literature in BIM shows a consensus about the main challenges faced in successfully implementing new innovations (i.e. BIM) in general, and information sharing in particular. These common challenges include lack of training team members, and resistance to change (see e.g.; Azhar et al. 2007; 2012; Dossick & Neff 2011; Harty 2008; Homayouni et al. 2010). Although the keystone of (BIM) is the communication process, which enables stakeholders, to collaborate effectively and deliver correctly the desired information (Xue et al. 2012), there is still some deficiency in communication processes within BIM projects. Moreover, to date there is relatively little research about the consequences of implementing collaborative approaches such as BIM on the existing communication channels used. In this respect, this study will identify 'what' happened to the existing communication channels and 'why'. In this study, the channel refers to *'as the medium of communication: the material through which the content is sent'* (Dainty et al. 2006:112). The research draws on three theoretical approaches: communication theories, team theory (Brennen et al. 2007), and cross-profession collaboration theory (Amabile et al. 2001). In doing so, selected factors from those theories have been addressed in relation to how relevant they are for recognising changes in communication channels. This study consisted of selecting 38 factors, which were grouped into three major categories (themes): the methodology of information exchange, collaborative team characteristics, and leadership.

In the communication literature, definitions of communication reflect at least two concepts. The first describes communication as the process of exchange information among sender and receiver to equalize information on both sides (Otter & Prins 2002). This approach focuses more on the ‘transmission aspects’ of the communication process forming a linear model and one-way process (Eckert et al. 2005). The second describes communication process as; *'transmitting messages from one person and the receiving (and successful understanding) of those message by another'* (Torrington & Hall 1998:112). Roger and Kinck (1981:63) describes the communication process as; *a' process in which the participants create and share information with one another in order to reach a mutual understanding'*. Emmitt and Gorse (2007:3) define communication as, *'sharing of meaning to reach a mutual understanding and to gain a response'* and this definition has been used widely in the communication literature. These definitions focus on, as Maier et al. (2008) referred to, obtaining an equal understanding, rather than measuring the information flow from-and-to the receiver. In the design process, sharing a mutually understating between participants is a fundamental prerequisite for any successful communication process (Eckert et al. 2005). In this regards, three communicational models are used. With growth in network speeds, information communication technology (ICT) opens opportunities for professionals to communicate in a different way; from texting, chatting, to visual communication (Sidawi et al. 2012). Beside this, in collaborative design environments, communication becomes much more complex, and professionals have numerous choices of various communication channels to employ (Gabriel & Maher 2002; Eckert et al. 2005). The availability and diversity of communication channels has been proposed by Gabriel and Maher (2002) as the main criteria for the success of collaborative communication. Nevertheless, in general, there are studies pointed to influential factors behind either the changes in channels in particular, or on the selection of those channels which may differ from one work environment to another. Despite the distinction of contexts, there is a consensus on some of those influential factors, for instance individual’s preference (Watson-Manheim & Belanger 2002; Gabriel & Maher 2002), organizational culture (Homayouni et al. 2010; Watson-Manheim & Belanger 2002) and physical environment (Dainty et al. 2006; Watson-Manheim & Belanger 2002). Interestingly, scholars’ views toward communication and collaboration (e.g. Ebrahim et al. 2009) also suggests that a team member is a leading unit in the process of communication and collaboration, who impacts and is influenced by the surrounding environment. Within the context of the design process, it is fundamental to understand the core role of team members within communication process; as being a sender and receiver.

In our study, the categorization process was conducted via sequential steps: 1) Break down all the most possible influential factors from the three literature areas; 2) Identify factor definitions from different sets of literature; 3) Group the factors into themes; 4) comparison and rearrangement of the factors (an iterative process); 5) Arranging them in a schedule in which classified them into three various themes, and under each theme, factors and sub-factors. Such categorization has been developed in order to address the possible impact of these sub-factors either to main factors, or directly to communication channels used. This process facilitated recognition of themes in the aim for developing an analytical framework, and in order to empirically examine the implications of BIM on communication channels used. These three themes are; Methodology of information exchange, Collaborative team characteristics, and Leadership. Importantly, the overlap between these factors within each theme, or across these three themes assists in developing questions for the pilot study in relation how these factors are relevant to change communication channels used. The factors have been extracted from three main sets of literature and relevant theories mentioned above; in terms of their potential influence on these main areas, and subsequently to their potential to change communication channels used. Surprisingly, despite considerable commonality between these factors, some differences appeared. The main aim of this research is to explore the implications of BIM execution on existing communication channels in the design process used by various professionals. In order to accomplish this aim, the objectives are; a) to understand how the communication process works; b) to identify various factors influencing change in communication channels used, and; c) to identify the communication channels enabled by BIM tools. To meet the purpose of the study, a case study strategy will facilitate to answer questions of 'what' happened, and 'why'. However, conducting a pilot study is also an initial step to refine the empirical questions, to identify suitable cases, and test the data collection approach for further empirical study.

2. Research Design

To meet the purpose of the study, a case study approach facilitated gaining a rich understanding of the research context (Morris & Wood 1991). Additionally, applying a pilot case study approach as an initial phase contributes in revising the data collection plans in order to be appropriate to the context of data, and rehearse procedures to follow (Yin 2009). Importantly, using a case study strategy from Saunders et al. (2009) perspective enables answering our research question in regarding of 'what' happened in communication channels, and 'why'.

Based on the reviewing the communication literature, employing a qualitative method is appropriate in seeking to understand communication channels, and this is usually achieved by using semi-structured interviews. Questionnaires were also developed to try and collect contextual data, and to refine the interview protocol. Observation is also common in communication research. However, this was excluded from the pilot study owing to the nature of Saudi’s society, which makes it difficult for this technique to be applied successfully, especially for female researchers. The data was collected from the three firms, and the last case was with a participant from the Ministry of health in KSA. The research was conducted using telephone interviews between June and August 2015.

This research was designed to pursue a sequential exploratory strategy, hence questionnaires followed by interviews employed. The two main objectives for initially distributing questionnaires were to identify the different kinds of communication channels used, and to measure the frequency of the use of these identified communication channels within BIM. Not only that but the quantitative data also helped further to crystallize our empirical interview questions by narrowing our focusing for the most likely influential factors (Creswell 2009). A triangulation strategy was employed within each case for the pilot study target which facilitated us to test the research interview questions for anything unclear or uncomfortable in relation to the context (Bryman 2012), which improved the questions quality (Yin 2009). It is worth noting that, the interview questions used were initially drawn from the literature, and tested with experienced professionals with BIM for more than 4 years. The interview questions were refined using the questionnaires’ responses providing insights into the numbers and types of channels and potential influential factors that were discussed in the interviews. The semi-structured interviews were conducted with an architect, BIM coordinator, and project managers across four organisations in order to get a range of viewpoints.

3. Analysis and Preliminary Results

3.1 Theme 1: Team characteristics

Resistance to Change: With regards to resistance to change, respondents referred to several factors. A recurring one was having had previous negative experiences with either particular approaches, software, or technology used to communicate. Besides this, negativity by some who had a previous negative experience shared their colleagues either at the individual or manager level was evident. However, based on the respondents' views, those people who 'resist change' have generated incorrect information regards, for example, the difficulty level, and effectiveness for desired tasks. It was thought that external software salespeople played a role in convincing individuals and management to adopt certain BIM communication approaches over others. Also, the BIM coordinator noted that *'We are obliged to follow up with the senior management directives particularly which related to the mechanism used for communication channels for information exchange'* (BIM coordinator, Case 1). However, it was thought that there has not been an obvious change in communication channels used, particularly at the level of individuals. In this respect, the project manager (PM) for the medical centre project in Riyadh, commented that: '*one of the challenges we were faced with is to get our employees away from using the communication channels were not listed in the planned communication model. Especially for large-projects cases, using normal E-mails system by some, were wasted the required information from the rest of the team members, especially if such person has been changed'* (PM, Case 2).

However there was a difference between the use of specific communication channels (such as email) and technologies. The participants were often surprised when asked about the role of spreading 'incorrect' rumours in changing or resisting changing the communication channels used. From their responses, the influence of rumour appeared more on technology use in general, rather than channels, in particular. In view of this, at the end such technology can involve use of a range of alternative channels. Therefore, the ultimate influence will be at those channels. Along with rumour impacts, there is an indication that change or impact is rooted in resistance or the influence of software vendors *'as one of the influential factors, most likely generated by the members who against to change, and a software salesman'* (BIM manger, Case 3). Individual preference was also important. Respondents noted that, *'Individual's preference is existing, playing a vital role on communication channels used, and appeared more obvious especially by the decision-makers'* (PM, Case 2). However, in another response, seems that the individual preferences are often constituted as a considerable challenges to the project manager. Thus preference led some professionals to remain using the hand sketches and the typical E-mails as a means to exchange and shared information, interpreted by the PM as due to a *'familiarity issue'.* (PM, Case 2; PM, Case 4). The last sub-factor is the presence of older generations within the teams. Within a BIM environment, and from the BIM coordinator's perspective *'the old generation refused to utilize a new technology, because they believed such technology will reduce their value and capabilities,..Yeah, don't surprise, this is what they believed'* (BIM coordinator, Case 1). Such resistance led other professionals to return back to use the traditional means which are not including on the communication protocols; for exchanging and sharing information. For instance, FTF meetings, hand sketches, E-mails and paper-based documents. Related to this, some responses showed the influence of the lack of computer skills (e.g. as related to Encoding-Decoding Knowledge). The BIM coordinator said *'sometimes we defined an assistant to do all the technical things for him; due to their deficiency on how to dealing with the technical issues, and the process for encoding-decoding.* This in turn, *'led some to use alternative channels….. thus, had made some changes in the type of communication channels used, and then on the workflow process'* (BIM coordinator, Case 1).

The diversity of skills, knowledge, and experience among professionals: As inferred from the dialogue with the BIM coordinator the influence of the diversity of skills, experiences, and knowledge among professionals on channels used is an important factor. He indicated that '*Because of the different skills and experience among the engineers; it was one of the reasons behind the misunderstanding of the outputs of the BIM simulation programme,.. especially appeared more on the technical and mechanical drawings stage...Oh yeah, in this case, some experienced professionals do not have any choice, except to follow the lower-skilled professionals on their way to design, by using a 2D projections (CAD),.. Certainly, in that case, they used E-mails as a channel to exchange rather than BIM server'* (BIM coordinator, Case 1). In the other hand, increasing the level of the professionals skills and experience, from the perspective of some respondents, contributes as well on making changes on communication channels. They were depended more often on BIM tools not only for exchanging data but also, for shared what other professionals were exchanged as well. Thus it contributes to *'reduce the dependency degree on the typical known communication channels, for seeking the desired information'*(BIM coordinator, Case 1).

The presence of competition among professionals: Within BIM collaboration, and when attempting to explore the interrelated impact between the role of rumour and changes in channels, rumour often appeared at the managers' level. However, at the individual level it was less obviously noticed. And, consequently referred to the existence of the high competition level among professionals, as interpreted by the BIM manager: *'In my experience, I haven't seen it much because there are some challenges, and the high level of competition. So, people just focus to be the best, yes to be the best.. the negative actor might be existed, but his influenced could not be noticed'* (BIM manager, Case 3). This suggest a more change oriented factor where the competition to perform can lead to individuals adopting new technologies and communication channels.

3.1 Theme 2: Leadership

It appears from responses that there is an important role played by the team leader or manager for making changes on the existing channels used for communication. Some of these are explicit and appeared more directly, and others indirectly. Nevertheless, they still have influenced the communication channels used. For instance team member selection (e.g. in terms of collaboration skills, experience, etc), availability or provision of training and educational courses, and lack of clear task coordination. Although classifying the influences type on communication channels as either is direct or indirect is beyond the scope of this pilot study some interrelated impacts have appeared which resulted from such factors. For instance, the individuals' differences for absorbing a new technology, and refusal to change by the old generation are restricting other team members to older (traditional-typical) types of communication to exchange and share the CAD files by E-mail, and paper- based documents. As was said by the BIM coordinator, *'In any project, normally team working at the same level of the performance and experience, and such selection is a core role of leader... Another strong factor is the type of the project, some projects are less difficult, the choice of the employees must be commensurate with their performance, background, experience, and skills'* (BIM coordinator, Case 1).

Another emerging factor is the lack of providing appropriate technical training, and educational courses according to the project and firm needs. Along with these, the lack of tasks coordination in terms of setting up a technical FTF meetings, especially at the outset of the project is considered as having some impact on channels. Typically, such procedure uses to clarify what the information requirements are, and who is responsible for what tasks...etc. However, the initial findings have not shown a direct influenced on the existed channels. There were expectations from the respondents, such as the project manager, that *'ambiguity around the provided information regarding what, and to whom they have to send such information… or sometimes, what the required information is, might lead to the need for documenting the communication process which will occur between the sender and receiver'* (PM, Case 4). However, when was being asked to provide examples, he commented by saying that *"Yes,.. Example, ok if the required information is almost enough to be sent via phone call, or through informal FTF conversation,.. but the sender, or might be the receiver were afraid, that the other person might be stated he didn't receive anything,.. oh yeah, in that case might the actor use some means which provide a documentation feature, let say, E-mail system'.* However, the initial findings have not shown a direct or clear influence for the lack of tasks coordination as a factor on the existing channels. It suggests, however, that it can impact on the trust level between participants, which subsequently leads to revert to alternative channels. For instance, using the E-mails as a substitute for the phone calls; for the documentation purposes. It is worth mentioning that all the participants without exception indicated the influential role of the decision makers in terms of identifying the communication protocols. Such protocols refer to the required communication channels, and the applications for project management to be used. Such decisions are according to the project, and the firm needs.

3.2 Theme 3: Information Exchange Processes

The responses indicated that interoperability, which BIM technology should provide, facilitated the process of sharing, exchanging and modifying information and documents. In terms of BIM changing the communication channels, the BIM coordinator said that *'The process became clear to all participants which facilitated communication process and information exchange...*

person has the ability to see all adjustments, instead of talking with each person and explaining individually to him ..Or, send a request for information via E-mail' (BIM coordinator, Case 1). Another PM stated that, *'the E-mail system has not used mainly as before in BIM-enabled projects'* (PM, Case 2). In view of this, it appeared that BIM has reduced not only the frequency and use for the FTF meetings but also reduced use of the E-mails system and hand sketches as well. Along with this, delayed responses by less active participants (e.g. old generations) and the differences in time zone were contributors. For instance, inactive participants resulted in shifting from exchanging the BIM models using a BIM server, to utilizing CAD and exchanging via E-mails. The majority of the respondents did not indicate a clear and direct impact of incentive and rewards structure in changing communication channels. However, one of them said that *'it might be influenced, especially on some cases. Such case, when the team member who did their duty correctly, and at the competitive time'.* In exploring how this might work, and influence channel use, The BIM coordinator said *'BIM has facilitated the process for sharing information around design details, but not shown of how they did these procedures'.* He consistently said that *'if the work procedures have done, or the technical issues have sorted it out, but in easier and faster way than what we planned to, normaly leader asked him for sharing these knowledge with other team members, and this person is rewarded for his efforts'.* In view of this, we could infer from his dialogue that the reward structure was contributing to improving the process for sharing knowledge, and addressing the lack of technical skills considered by respondents as one of the influential factors towards changes on channels used. Consequently, the rewards structure eventually influenced the communication channels used. In addition, the responses are shown to influence both the project characteristics (e.g. project's needs, scale, types, and the level of complexity), and the contract form for the partnership agreement. In view of this, the lack of information provision regards the contractual agreement, in terms of clarifying the communication protocols such as the number of meetings, communication means (e.g. channels, project management applications) had made changes on communication channels according to both of the project managers for Case 4; and Case 2.

4. Discussion

In an effort to illuminate the identity of the influential factors implicated in changes in communication channels, we performed a case study approach for (4) cases with (4) interviews (4) interviews and (8) questionnaires. The above analysis from the preliminary interviews yields several findings that relate to the previous research in the communication, team, and collaboration literature. In this regards, the empirical result of this research uncovers some emerging influential factors as shown in Figure (1). The evidence from the case studies supports the literature suggesting influential factors, but in our study their type of effects were different. Our empirical findings revealed sets of relationships in relation to the aspects for communication, teamwork, and collaboration, and subsequently their potential influences on communication channels used. Although the evidence from the case studies supports the literature suggesting that individual preference, resistance to change, and organizational culture are important, it is worth noting that, the factor we have termed 'spread of rumour', has not been addressed yet on communication literature but appears an influential factor behind channels changes during the design process. Our findings disclosed that it played a critical role at the level of the decision maker (i.e. manager) alongside the influential role of the software vendors in selecting technologies and therefore communication channels. However, the influence of rumour was more difficult to see at the level of individuals. This is due to, as respondents referred to, the presence of high competition level among professionals within BIM work environment. This resulted on developing their skills constantly, and following up the managerial instructions.

Figure 1: The emerged influential factors, and themes

To illustrate this, the individual's preference for using some certain communication channels instead of others was due to several factors, with the familiarity factor as one of the main causes, despite having training and educational courses. Our findings are consistent with the findings of Watson-Manheim and Belanger (2002), despite the context being different, that there is consistency in term of factors, and in the interpretations behind impacts and changes. The familiarity factor appeared more clearly with the older generation professionals who are claimed to have a lack of computer skills. These previous factors constitute the action of 'resistance to change'. Within a BIM-based project the relative absence of hand sketches as a 'familiar technique' was considered less acceptable for older generations. It was found that the need for using hand sketches as non-verbal communication paired with BIM tools is being used less than before (i.e. non-BIM cases). But our findings suggest, in this respect, that the absence of such techniques might constitute a threat to older professionals' status and the level of their hand-drawing skills developed during their careers. Such skills may be the very reason why they arrived at such position in their companies. Alongside this, we might also consider the importance of hand sketches as a visual language as Sebastian (2011) stated, and a vital communication tool from the view of Homayouni et al. (2010) which is used to support clear communication during meetings. Although FTF meetings may be the most preferred means to communicate (Gabriel & Maher 2002), our findings are consistent with Dossick & Neff (2011) in terms of hand sketches being used less during meetings in BIM projects. Surprisingly, the skills, experiences, and knowledge as high or low for the team members, have contributed to making changes on communication channels used. To illustrate that, highly skilled professionals can shift faster between using the traditional channels (e.g. E-mails system, phone calls) to utilizing BIM tools (e.g. BIM server, open request on Revit® building design software). In contrast, at the low-level skill, the need for face to face discussion remained along with emails for making inquiries. The main feature of BIM as an interoperable system, not only potentially produces a free error design, but also facilitates sharing what others have exchanged, pointing to problems identification and inquires directly in the Rivet models. These features not only reduce design errors but also, reduced the dependency degree on (one to one) meetings, emails, paper-based documents (e.g. hand sketches) and informal discussion. These findings seem to be agreed with the findings of Dossick & Neff (2011) in examining the changes occurring by using BIM. In addition, another influential factor is the documentation requirements and the need to record the communicational content to provide evidence for the process of exchanging the official information among professionals. Particularly, it found the work environment sometimes characterized by a lack of task coordination among professionals. Furthermore, if there is a lack of trust, there is arguably a need to record the process, which is consistent with Watson-Manheim & Belanger's (2002) findings regarding influences on channels choice. However, this could also be attributed to ineffective leadership, as indicated by Ebrahim et al. (2009), and Amabile et al. (2001). Another common influential factor from the communication aspect, is the communication protocol's form included in the contractual project requirement, and partnership agreement. Our findings are consistent with Emmitt & Gorse (2003) in that the definition of the formal communication channels are associated with the contractual requirement for each project. The communication protocol, as our results revealed, differed according to project types, project scale, partner type, and the level of complexity. This diversity in protocol resulted in changes of the channels used from context to context. These findings seem to be agreed with Dainty et al. (2006) in arguing that the need to expand communication across organizational boundaries is an inevitable consequence of increasing the project scale, and subsequently results in expanding types of channels used. Furthermore, our findings indicate that the project management applications and their variety are based on the project type or firm's need which can cause differences in communication channels used from context to context. According to the questionnaire results, our study reveals some of the current types use of communication channels, and how often they are being used on the BIM-based project. However, our preliminary results did not allow us known about the percentage rate of used for each channel or whether this percentage rate for a particular channel is decreased, or increased after implementing BIM. However, overall the use of email, FTF meetings, video conferencing and phone calls are still employed within BIM environments, but the use rates are less than non-BIM projects.

5. Conclusion

This paper explored our key question of what happens to communication channels with BIM-enabled projects and why, by employing empirical case studies on the emerging role of the technology (i.e. BIM) on communication processes within design. Our study presented a comprehensive list of factors which have been examined by the relevant theories; communication, teamwork, and collaboration literature, to date. Such factors categorized according to their influences in such areas of literature which in turn, facilitated the previous process of data analysis. This study identified 38 factors, which can be considered as a guide to figure out the potential changes on communication channels used, as a new approach that has not been addressed yet in the current literature. Such addressed factors are the fundamental step in identifying the changes on channels for any new technology. This study provides a first step in this direction. Based on such analysis for the pilot case study and literature, there is some commonality on the influential factors across various research areas. However, the results presented in our study are seen as an initial attempt, therefore more extensive research needs to be undertaken to understand the implications of BIM. In this respect, this study concludes that relying on communication theories only, such as were used initially, are not sufficient to understand and subsequently interpret the occurred changes thoroughly in a complex environment (i.e. BIM). Therefore, the employing of the three communication theories, although there are relatively diverse, including teams and collaboration, have provided another dimension and insights to our study. Finally, a few limitations of this pilot study should be noted. First, the much of data is reliant on a relatively small number of participants' feedback. Second, there is no substantive quantitative data to help verify these views, for instance with indications for the percentages rate for using each channel. These will be considered as further research is undertaken.

Abstract

Projects in the construction industry typically involve complex information flows from early design, through construction, to facility management (FM). Building Information Modelling (BIM) tools and workflow processes are considered key enablers for collaboratively managing such information across phases of the project lifecycle. With the increased adoption of BIM by the construction industry, there are heightened expectations for increased engagement of facility managers (FMs), users and clients in the BIM process. This is based on the proposition that BIM can benefit the operational phase of a building, which contributes the most to the building lifecycle in terms of overall cost, sustainability and usability. The study aim was to investigate current levels of understanding and adoption of BIM by facility managers in practice. Three research questions were investigated: (a) *How client and FM engagement with BIM workflows can be improved through early contemplation of their requirements*; (b) *what are the perceptions about BIM and its potential impact on the FM industry from an FM, user and client perspective* and (c) *what information is required by FM from the BIM process to maximum optimisation of assets in the operation phase*.

Mixed research methods, including: a literature review of academic and industry publications (e.g. case studies, industry best practice, standards and guidelines), an online survey of FM professionals and focus groups, were used to address the posed research questions. The findings highlight the need for further education regarding BIM guidelines and standards. In particular, new and more FM/client-focussed BIM strategy documents, EIR and other templates are required. Many existing templates (e.g. EIR) are not focused on client's needs. Guidance is required on developing BIM strategies based on understanding the client's Organisational Information Requirements (OIR) and Asset Information Requirements (AIR) in order to develop an EIR that specifies what, when and how information should be delivered. This will improve timely decision making during design and ensure that the right and correctly structured information is delivered to clients at handover for their Asset Information Model (AIM) to help optimise the operation of their assets.

Keywords: Facility Management (FM), Building Information Modelling (BIM), Employer`s Information Requirements (EIR), Asset Information Model (AIM)

1. Introduction

BIM is driving rapid change throughout the design and construction (D&C) industry and increasingly is becoming the chosen process across Europe and the wider world for the planning, D&C of buildings and infrastructure projects. Many D&C professionals have already gone through the paradigm change required to adopt and implement BIM. However BIM has not yet had a significant impact on the FM industry. This is creating a growing knowledge gap about BIM between the D&C and FM industries. The BIM workflow process when managed properly should start with a clear specification of the client's asset operation and maintenance (O&M) information needs in the EIR. At present, this is not happening, as many clients and FMs do not yet have adequate knowledge and experience to fully engage in the BIM process. If this problem is not addressed many potential benefits of BIM may not be fully realised.

2. Literature review

There is growing recognition that BIM can deliver significant economic, social and environmental benefits in the creation, O&M of assets and buildings, especially when value is considered over the whole life cycle. The UK Government for example recognised the added value BIM can deliver in its 2011 Construction Strategy as an aid to ensuring "the country gets the social and economic infrastructure it needs for the long-term" (Cabinet Office, 2011). With respect to ROI and who benefits most in the BIM process; the *SmartMarket Report* (McGraw Hill Construction, 2014) reports "three quarters of all contractors' surveyed report a positive ROI on their investment in BIM". However the key beneficiaries of BIM are ultimately clients and end users (Eastman, et al., 2011). Other research looking at ranking stakeholder financial benefits in relation to BIM has indicated that clients benefit most financially from BIM followed by FM (Eadie, et al., 2013). This is because BIM models and their associated information can be used throughout the whole lifecycle of buildings, infrastructure and assets (BSi, 2013). This is critical to understanding the most significant savings and benefits can be realised over the longer operational use phase.

In relation to whole life costing, research shows up to 80% of the O&M cost of an asset can be influenced in the first 20% of the design process (ISO, 2008). FM operational expertise and input is thus critical in the early stages of design to avoid expensive decisions which can have long lasting implications (Ashworth, 2013). Other research shows that FM and the O&M of a building equates to 60% of the overall costs of a project (Akcamete, et al., 2011). They suggest significant financial gains can be achieved by specifically targeting this aspect of a project. Clients, in particular, can achieve worthy benefits on their construction projects by adopting BIM technologies and workflows to guide their delivery process to higher quality and performance for a whole building life cycle (Eastman, et al., 2011). Research also shows 39% of contractors assign greatest value in projects to adding O&M data to models for the owner (McGraw Hill Construction, 2014). However, research shows that BIM adoption in the O&M phase is currently less than 10% and potentially significant unrealised benefits could be achieved if more focus was given to the impact of BIM in the O&M phase (Eadie, et al., 2013).

To help stakeholders the UK government has put in place a framework of BIM standards and guidelines for the BIM process. PAS 1192-2 (BSi, 2013) states the start of the BIM process should be a "clear understanding of the client`s OIR and AIR" and that one of the "fundamental principles of level 2 information modelling is the provision of a clear EIR". It defines the EIR as a "pre-tender document setting out the information to be delivered, and the standards and processes to be adopted by the supplier as part of the project delivery process" and that the "EIR should be incorporated into tender documentation to enable suppliers to produce an initial BIM Execution Plan (BEP)". The Government has provided an EIR template for stakeholders (BIM Task Group, 2015), however the author believes that a more client focused template is required.

PAS 1192-3 (BSi, 2014) describes the ultimate purpose of the BIM process is to "provide information into the client Asset Information Model (AIM)" which should be "the single source of approved and validated information related to the asset(s)". BIM can provide a fully populated asset data set for CAFM systems and therefore reduce the time needed to obtain and populate asset information. This enables FMs to achieve optimum performance more quickly, reduce running costs, and refine target outcomes (BIM Task Group, 2015). The data should include: "data and geometry describing the asset(s) and the spaces and items associated with it, data about the performance of the asset(s), supporting information about the asset(s) such as specifications, operation and maintenance manuals, and health and safety information". However clients/FMs are the only stakeholders that ultimately understand the client needs, and can specify these for the EIR at the start of the BIM process. BS8536 (BSi, 2015) aims to help, promoting "the early involvement of the operations team or FMs and by extending the commitment of the D&C team to post-handover asset aftercare to ensure its correct, safe, secure and efficient operation in line with environmental, social, security and economic performance targets". Thus to ensure the BIM process works fully, the client/FM have to be included early.

With respect to FM knowledge and awareness of BIM; surveys such as the BIM4FM survey (A working group of BIM Task Group) have tried to understand the perception of BIM by FM, end users and clients. The survey found that "although people are aware of BIM there is still a significant audience that is unsure of how BIM is used within the built environment" (BIM4FM, 2013). 63.2% of respondents were "unsure of whether their organisations plan to use BIM in the future". The NBS National BIM Report 2015 (NBS, 2015) also provides some useful insights from the construction industry perspective on BIM: 50% said they were currently using BIM and 95% of respondents believe "they will be using BIM within 5 years". However 67% also reported that "the industry is not clear on what BIM is yet". Other research work has shown that many D&C professionals (93.6%) agree with the UK Government's BIM strategy decision to mandate level 2 BIM on all public sector projects by 2016 (Eadie, et al., 2015).

3. Methodology

A mixed method approach was used; 1) a literature review to identify issues and to design the online survey form, 2) A survey conducted through two Swiss FM associations with the aim of understanding and establishing a benchmark of the understanding and adoption of BIM and how it will impact on the FM industry (399 people accessed and 68 completed the survey), 3) A focus group workshop titled "*FM and BIM in Research and Practice*" using results from the questionnaire to select topics for discussion. Three separate focus topics were discussed with the aim of establishing the information needs/outputs to inform the creation of a more FM client-orientated EIR. Topics were: (a) *FM operational:* information needed for space management? (b) *FM financial*: information needed for decision making? and (c) *FM personnel*: training/skills needed to be able to engage with the BIM process? A final focus group with all attendees then discussed, reflected and summarised the individual group findings.

Twenty participants engaged in the focus groups with stakeholders across the whole life cycle. International representation came from; UK, Switzerland, Germany, Denmark, Norway, Netherlands and the US. Participants were from professional bodies; IFMA, the Danish FM Network (DFM), the Norwegian FM (NBEF) and the British Institute of Facility Management (BIFM) Soft Landings team. FM and D&C practitioners attended from; BAM UK, BAM Deutschland AG, Mace Macro, ISS, Halter AG, eneco, Robertson FM, FES FM, Auwiesen Immobilien AG, UniversitätsSpital Zürich and Glasgow Life. Academics attended from; Zurich University of Applied Sciences (ZHAW) and the Netherlands Hanze University, Groningen.

4. Survey findings

There were 68 fully completed online questionnaires, a response rate of 17.04% from the 399 people who opened the survey. The respondents included stakeholders over the whole life cycle of a building: 18 planning consultants, 15 internal FM providers, 14 building owners/agents, 9 external FM providers, 3 CAFM[1] suppliers, 2 architects, 2 investors/clients, one building contractor, one procurement manager, one data manager, one surveyor and one government administration officer. The profile of company size by no of employees is shown in Figure 1. The majority, 38.2% of respondents were from companies with 1000+ employees.

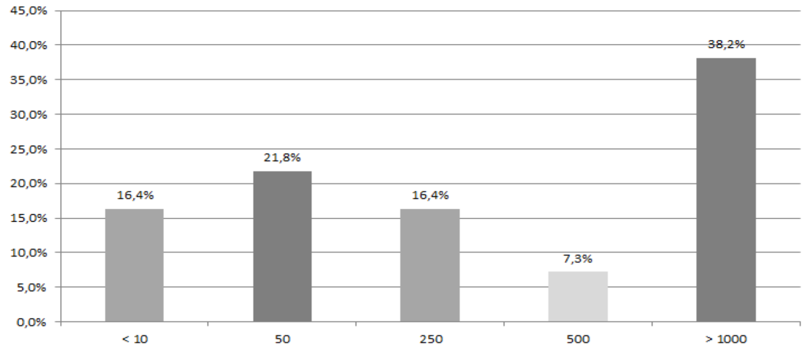

Figure 1: Size of company by number of employees

Respondents :down of the type and size is shown in Table 1.

Table 1: Type and size of real estate managed by the respondents

Type of space	**Total m2 (Gross)**	**Average m2 (Gross)**
Office / administration	7,707,293	296,434
Laboratories / industry	2,395,407	140,906

[1] CAFM: Computer Aided Facility Management

Residential / flats	2,008,700	223,189
Retail	1,818,500	363,700
Public offices and buildings	1,805,025	361,005
Other	1,759,500	351,900
Hospital / care home	1,730,000	173,000

They were asked about general knowledge/experience of BIM and how they perceive BIM will impact on the FM industry. With respect to experience: 41.2% had no experience with BIM, 33.8% had some, and 25% gave no answer. The majority of respondents (55.4%) as shown in Figure 2 believe BIM will have a significant impact on the FM industry within 5 years.

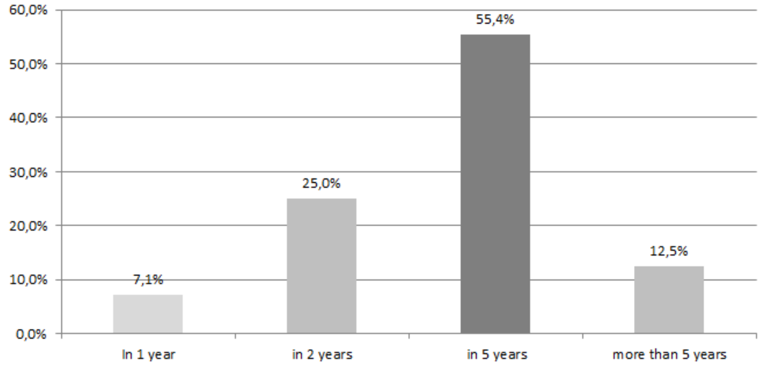

Figure 2: Timescale for BIM to impact on the FM industry

The respondents were then asked about their perception and understanding of BIM with a series of questions (previously used in the NBS survey). Table 2 shows their responses. A Linkert scale was applied and the mean score calculated using the numerical values (1=disagree, 2=somewhat disagree, 3=somewhat agree and 4=agree). The table scores were ranked according to the mean score.

Table 2: Perception and understanding of BIM

Question/statement	**Agree %**	**Somewhat agree %**	**Somewhat disagree %**	**Disagree %**	**Mean score**
The FM industry is not sure what BIM actually is (n=54)	33.3	57.4	7.4	1.9	3.22
BIM is all about real time collaboration (n=53)	26.4	41.5	17.0	15.1	2.79
BIM is all about software (n=54)	3.7	13.0	53.7	29.6	1.91
BIM is for new buildings not existing buildings (n=55)	3.6	14.5	27.3	54.6	1.67
BIM is simply a synonym for 3D CAD drawings (n=55)	0	7.3	16.4	76.3	1.31

Respondents were asked about their familiarity and knowledge of the Governments BIM guidelines and standards as well as the Swiss BIM guideline "SIA Merkblatt 2051 BIM" which is currently in development. The answers are shown in Table 3:

Table 3: Knowledge and familiarity with BIM guidelines and standards

Guides and Standards	**%**
Swiss guideline SIA Merkblatt 2051 BIM (In development)	25.0

ISO 15686 Building and constructed assets – Life cycle costing	13.2
Other: (See below for details)	7.4
PAS 1192-2: 2013: Capital/delivery phase of construction projects using BIM	7.4
BS 1192-4: Fulfilling employers information exchange using COBie: code of practice	5.8
PAS 1192-3: 2014: Operational phase of assets using BIM	4.4
ISO 55000: 2014 Asset management	4.4
CIC BIM Standard Protocol for use in projects using Building Information Models	2.9
CIC Guide for Professional Indemnity Insurance when using BIM	2.9
CIC Outline Scope of Services for the Role of Information Management	0

Other guidelines and standards the respondents were familiar with were; the Swiss “KBOB Guideline for Building Documentation in Buildings”, the “Penn State BIM Planning Guide for Facility Owners”, the “NATSPEC” document suite and the German “Research Initiative ZukunftBAU”. Respondents were also aware of various online forums promoting BIM best practice such as the UK BIM Task Group, BuildingSMART, COBIM from Finland etc.

Respondent’s perceptions of the potential benefits of BIM to FM are shown in Table 4. A Linkert scale was applied and the mean score calculated using the numerical values (1=disagree, 2=somewhat disagree, 3=somewhat agree and 4=agree). The table scores were ranked according to the mean score.

Table 4: Potential benefits of BIM to FM

Potential benefits of BIM to FM	**Agree %**	**Somewhat agree %**	**Somewhat disagree %**	**Disagree %**	**Mean score**
Direct data transfer to FM CAFM/other systems (n=50)	50.0	44.0	2.0	4.0	3.72
Simulations e.g. energy use, fire evacuation etc. (n=51)	47.1	37.3	15.6	0	3.61
Improved transition construction to operation (n=55)	56.4	30.9	7.3	5.4	3.58
Visualisation of buildings for customers/investors (n=55)	49.1	40.0	9.1	1.8	3.56
The use of BIM may improve profitability (n=42)	26.2	50.0	19.0	4.8	3.55
Faster cost and life cycle cost estimation capability (n=51)	41.1	39.3	15.7	3.9	3.47
Improved space management (n=53)	41.5	37.7	18.9	1.9	3.43
Improved asset maintenance response times (n=52)	36.5	44.2	11.6	7.7	3.37
Reducing the cost of insurance for buildings (n=40)	7.5	25%	52.5	15.0	2.90
Improved health & safety for operational FM tasks (n=47)	10.6	29.8	42.6	17.0	2.74

Respondents were asked how they thought FMs could make best use of BIM to help FM. The results were ranked based on frequency of mentioning and are shown in Table 5. Respondents also identified other potential uses as: exact planning during construction, quantity surveying, data-imports for CAFM tools, business continuity and service and maintenance optimisation.

Table 5: Ranking of possible uses of BIM by facility managers

Possible uses of BIM by FMs	**% Response**

Life cycle costing	28.85
Cost savings	26.92
Increasing operational efficiency	26.28
Reduction of carbon emissions and energy savings	12.82
Other	3.21
I don’t know how facility management will use BIM	1.92

The respondents concerns with respect to the adoption and implementation of BIM were ranked based on frequency of mentioning as shown in Table 6. Other concerns identified were: legal liabilities, early FM involvement, uncertain ROI, stakeholder buy in, familiarisation with BIM, data management and the danger of BIM creating a “data cemetery”.

Table 6: Concerns regarding BIM and FM

Concerns regarding BIM	**% Response**
The cost of implementation (time and resources)	19.61
Data management	19.61
Availability and knowledge about BIM guidelines and specifications	15.03
Basic BIM knowledge/training and its benefit to our operation	14.38
The incorporation of BIM into contracts and legal concerns	12.42
Unfamiliar technology and integration with CAFM tools	10.46
Other	8.50

Respondents were asked about their perception of possible barriers to the adoption and implementation of BIM. Their responses were ranked based on frequency of mentioning and are shown in Table 7. Other possible barriers included: fear of change, people wanting to stick to traditional work practices, if we can really achieve collaborative working, needing to change existing fee systems, lack of BIM standards, ROI on BIM, lack of coordination regarding implementation of BIM in the FM industry and ongoing management of BIM models and associated data in the operational phase.

Table 7: Possible barriers to the adoption and implementation of BIM

Possible barriers in the adoption and implementation of BM	**% Responses**
Lack of internal expertise	23.48
Costs	21.74
A lack of demand from clients	20.00
Other	18.26
BIM is not always relevant to our projects	9.57
The projects we work with are too small	6.96

5. Focus group findings

The findings of the three separate focus groups with respect to the selected FM topics are summarised in the subsequent three sections. These are followed by key issues raised during the whole group’s review of the findings and observations.

5.1 FM operational requirements for space management

Space reporting**:** FMs need information which allows the quick generation of tailored reports identifying all building and asset spaces by: name, type, size, volume, finishes and materials and where appropriate ownership. The space information should be delivered in a hierarchical manner with a unique and agreed "space naming system" specified by the customer. Space should be appropriately zoned to allow zoning for fire, security, rental and other purposes. Space flexibility information should be included for potential future change. The information should allow FMs to understand the quality level of the space and demands to be made on it. Ideally BIM models should link directly to CAFM tools to allow visualization of spaces and assets within the CAFM software. This will save on time in visiting spaces to address problems.

Space inventory and cost data**:** The information should include data/information on all assets within each space. Each asset should then have attached information detailing: asset/serial no, cost, life expectancy, warranty period, service costs, manufactures maintenance requirements etc. as well as who is responsible for each asset (in terms of purchase, replacement and servicing). This information should be available well ahead of building handover to allow transition planning and FMs to calculate detailed operational and replacement costs and the ability to benchmark costs and future performance, tenders and for managing projects.

Space concepts, logistics and use**:** FMs need to have a clear understanding of the design logistics planning concepts for the movement of people/equipment, access routes and space for changing pieces of plant and equipment at the point they need to be replaced. FMs need all relevant information for the planned use of buildings/assets/spaces at handover as well as how each space could be used in the future. This should include how easily spaces can be reconfigured to accommodate flexibility and change of use.

5.2 FM financial requirements

Asset and life cycle cost data**:** the BIM model should include all cost information for assets i.e. replacement and installation costs, life expectancy, service/maintenance costs etc. This will benefit FMs for both daily operational management as well as forward financial planning for asset replacement or refurbishment. This data should be available at the relevant data drops in the established design process (RIBA stages and COBie drops). Ideally this information should be migrated into the chosen CAFM tool by the construction contractor well before handover.

Commercial model data**:** It was acknowledged that there could be sensitivities around the issue of commercial information, but having full transparency of the builders procurement cost data will allow FMs to better understand and build their FM operational and asset replacement programmes faster and more accurately for clients.

Cost sensitivity and design efficiency**:** FMs should work closely with other stakeholders during the process as outlined in BS8536 from initial development of the EIR to identify information and concepts in the BIM process ensuring that site/building specific issues such as transport, logistics etc. are thought through from an FM operational perspective. This will help ensure cost accuracy, less change requests and provide regular feedback mechanism for more accurate sensitivity analysis with checks made as appropriate at every stage/phase.

5.3 FM personnel: training and skills requirements

***BIM training*:** The group reported most FMs have heard of BIM but have little or no practical experience. Members of the BIFM Soft Landings team reported that BIFM are currently working on guidance documents to help FMs develop an EIR and fully engage with the soft landings process. The FM staff should have training with respect to the BIM process and management of BIM models and associated data to ensure they can access, manage, amend and update data during the transition and operation phases. A key issue discussed was the need for FM to understand how the data will feed into CAFM / BEMS (BMS) and other FM systems. It was felt there was a risk that many of the potential benefits may not be realised due to poor training and a lack of understanding as to how the models can be used to FM advantage. If FMs are not able to interrogate BIM models there was concern about models being kept up to date.

***A FM handover training roadmap*:** should be a requirement in the EIR to ensure FM teams are fully involved with commissioning at the right time and receive appropriate pre-handover training. The group reported that adequate funding, resource and time for training are often lacking in projects and regularly squeezed into unrealistic timeframes at the last minute as D&C teams struggle to meet project deadlines. The FM team need to acquire BIM skills but also should have a different attitude and approach to embrace the possible benefits of using BIM models. The FM team should have adequate training and involvement during the design process whilst the models are being developed to allow them to give their clients feedback and suggested improvements as well as becoming familiar with the models and developing the skills to use them for visualisation and other uses.

***Post Occupancy Evaluations (POE)*:** FM staff should be included in the planning of POE for the Soft Landings process to ensure they understand how the BIM process and models will be used to help verify that the building is performing as per the design criteria and to understand any variations that may occur due to occupant behaviour or other factors.

5.4 Focus group discussion on the impact on the EIR

***Defining FM information needs/outputs*:** the whole group agreed it was difficult to tie down the required information needs/outputs and when they would be needed in the BIM process.

Guidance and templates: the whole group felt it would be beneficial to have specific guidance and templates to help clients/FMs draft and complete an FM/client-orientated EIR.

6. Discussion

With respect to research question (a) *How clients and FMs engagement with the BIM workflow process can be improved through the early contemplation of their requirements*?: the research confirmed a key issue impacting on both the D&C and FM industries is both are still not sure what BIM actually is. The research found that 57.45% of FMs and clients (somewhat) agree with this. This broadly aligns with the BIM4FM survey reporting that 63.2% of FMs were uncertain if their organisations had plans to use BIM. The 2015 NBS survey shows the D&C figure even higher at 67%. The research focus group feedback highlighted “most FMS have little or no practical experience of BIM”. This was backed up in the survey which indicated 41.2% have little or no practical experience of BIM. Other research from the D&C industry reports less than 4.05% use of BIM for FM operations with 54.05% never using it for FM (Eadie, et al., 2015). This is not surprising when we consider these figures together with the fact that most FMs have not yet had any significantly exposure to BIM projects and although many FMs have heard of the raft of Government BIM standards and guidelines, many have a poor understanding of the detailed content. This aligns with the focus group feedback that “as a community FM is on a sharp learning curve with respect to understanding how the BIM will impact on their FM operations”.

The NBS 2015 survey reports a general increase in D&C knowledge and adoption of BIM with 75% of respondents aware of the UK Government defined levels of BIM and 59% claiming to be already achieving level 2. Other research found this figure to be 53% (Eadie, et al., 2015). Not surprisingly the RIBA Plan of Work (RIBA, 2013) was noted as the most common BIM standard/publication used by D&C organisations. PAS1192-2 (BSi, 2013) is also well known. Other research (Eadie, et al., 2015) found the most common standard was BS 1192-7. However with respect to the support of FM in the operational phase the NBS figures did not look so good. Only 12% in the D&C industry have passed on “the model to those responsible for continued management of the building”. Also the use of COBie (which is essential for capturing data for FM CAFM systems) decreased slightly on the previous year with less than 1 in 5 respondents using COBie. The top 4 barriers to using BIM were (74%) lack of in-house expertise, (67%) lack of training, (63%) no client demand and (56%) cost. However “contrary to what the literature about the potential of BIM for FM, current state suggests it is rarely used with a very low figure (4.05%) (Eadie, et al., 2015). This all indicates FMs and clients need to educate themselves about the BIM process and understand how BIM standards and guidelines can be used to their own advantage in generating FM/client-orientated BIM strategies and EIRs.

With respect to research question (b) *what are the perceptions about BIM and its potential impact on the FM industry from an FM, user and client perspective?:* the time scale of 5 years seems to be a common figure. The research showed 55.4% of FMs feel BIM will have a significant impact on FM industry within 5 years. According to NBS, 95% of the D&C industry believe they will be using BIM on projects in 5 years. The figure of 5 years also ties in with other research indicating that “although BIM usage will have increased by 2016 it will not have reached the 100% level 2 stipulated by the Government” (Eadie, et al., 2015). With respect to the general perception and understanding of BIM, the focus groups and survey highlight that although a detailed knowledge of BIM guidelines and standards is lacking most FMs were general informed about BIM basics with (41.5%) somewhat agreeing BIM is about real time collaboration. Regarding software; (53.7%) somewhat disagreed that BIM is all about software and the majority of FMs agreed BIM is not only applicable to new buildings (54.6%) and also the majority (73.6%) believe BIM is not simply a synonym for 3D CAD drawings.

Concerning the main uses of BIM by FMs the research broadly aligns with the previous BIM4FM survey findings. Life cycle management was ranked top in both research surveys. Making cost savings was ranked 2nd in the research (3rd in BIM4FM survey) and increasing operational efficiency was 3rd in the research (2nd in the BIM4FM survey). Carbon reductions were in 4th place in both surveys. Regarding the key concerns there was some alignment with the cost of implementation ranking number 1 in both surveys. However the BIM4FM survey ranked integration with current technology and CAFM as 2nd whilst this was 6th in the research survey. Training and knowledge concerns were ranked 3rd in the BIM4FM survey and 4th in the research. Data management was ranked 2nd in the research and 3rd in the BIM4FM survey.

With respect to research question (c) *what data/information is required by FMs from the BIM workflow process to maximum optimisation of assets in the operation phase;* this was more difficult to address. A few FMs were aware of the Government EIR templates but most did not have a detailed understanding. Those that did commented that the templates are not FM/client-orientated. The individual and whole group feedback demonstrated how difficult it was to identify specific FM information/outputs in a clear way that would allow succinct wording for an EIR document. It was felt further research work is required in this area and it was hoped the development of new templates for BIM strategies and EIR documents by BIFM and Government bodies will help FMs in creating "client-orientated" EIR documents.

7. Conclusions

The research indicates that although BIM is rapidly becoming the norm in the D&C industry, the majority of FMs and clients do not yet have a thorough knowledge of the available BIM guidelines, standards and workflow processes and few have any practical experience of BIM. There is a need to further educate the FM industry to address the potential growing knowledge gap between the D&C and FM industries. To help achieve this further research should investigate the development of FM/client-focused BIM strategies and EIRs. FMs should engage early in the D&C process, and assume ownership of the EIR on behalf of their clients to ensure client and FM information needs are adequately addressed. This will help ensure the right information is delivered and structured in the right way to use in existing FM CAFM systems. There is a real danger that if these issues are not addressed many of the potential benefits of BIM may remain unrealised in the operational phase, especially if information from the BIM process ends up in a data cemetery due to a lack of BIM knowledge and skills in the FM industry.

Abstract

Value chain analyses are utilized to study the value process production of companies. For the construction industry, several change agents are affecting the value chains in usage. To address this development, this article reviews what is considered to be the state of art in additive manufacturing methods and 3D measuring technology. Consequently, a new value chain is proposed for construction employing these technologies which is then compared to the current value chain in the construction industry. These emerging technologies may radically alter the construction industry and the way in which consumers procure construction services. Accordingly, disruptive technologies, digitalization, and servitization will likely have a profound impact on the business models and value networks in construction.

Keywords: value chain, additive manufacturing, 3D measuring, augmented reality, digitalization

1. Introduction

A value chain is a model of the corporate value forming process, first introduced by Professor Michael Porter (1985) in his book, “Competitive Advantage: Creating and Sustaining Superior Performance”. For the last 30 years, it has been applied to understand and analyze industries and has proven a useful mechanism for portraying the chained linkage of activities that exist within traditional industries, particularly that of manufacturing. It has also to a great extent framed modern thinking about value and value creation.

Accordingly, value chain analysis is a process whereby a firm identifies the primary and support activities that add value to its final product and then analyzes these activities to reduce costs or increase differentiation. The value chain represents the internal activities in which a firm engages when transforming inputs into outputs. In this chain, each step of the production process is identified and described for an individual product starting from its source materials, and each of these nodes in the value chain causes an incremental increase in the overall value. These nodes can be physical production steps, such as weaving cotton, or they can be intangible steps, such as associating the product with a brand. Until the 1990s, a central component in value creation for a company was the generation of economic benefit for its shareholders. However, during the previous two decades, the production of customer value has now become the core aspect in value creation. This has been coupled with the application of methods from design and the social sciences to branding and service development activities. This shift in focus has in turn led to the multidisciplinary study of intangible value creation wherein value is understood to be produced by all actions of a company, and formed on individual, social, and societal levels (Tikka & Gävert, 2014).

The concept of a value chain has assumed a dominant position in the strategic analysis of industries. However, the model is underpinned by a certain value-creating logic, and its application results in accordant strategic postures. As products and services have now become ever more dematerialized and the value is ever more created in networks and alliances, the value chain concept can no longer properly uncover all sources of value. As such, the focus of value creation and analyses has now shifted to value networks, meaning that value is co-created by a combination of players in the network. Adopting a network approach, organizations focus not on the company or the industry, but rather on the value-creating system itself. In contrast to the value chain logic, these functions are performed simultaneously rather than sequentially, and mutual adjustments are required with respect to network scope, capacity, and the technical properties of the concurrent services. The value network is a business analysis perspective that describes the social and technical resources within and between businesses. The nodes in a value network represent people (or roles). The nodes are connected by interactions that represent tangible and intangible deliverables. These deliverables take the form of knowledge or other intangibles and/or financial value. These value networks thus exhibit interdependence and account for the overall worth of products and services (Peppard & Rylander 2006; Allee 2000 & 2008; Santoni & Taglioni, 2015).

Beyond the value network approach, Porter has further expanded his value views to include shared value which means that value creation exists not only for companies and customers but to the larger society. He suggests that companies often remain trapped in an outdated, narrow approach to value creation. Focused on optimizing short-term financial performance, they overlook the greatest unmet needs in the market as well as the broader influences on their long-term success. Companies too often ignore the depletion of natural resources vital to their businesses, the viability of suppliers, and the economic distress of the communities in which they produce and sell (Porter & Kramer, 2011).

The construction industry has also faced challenges. Originally focused on industrial logistics, construction companies are transforming into service businesses. Following this transformation, a construction company becomes primarily a service provider from the point of view of its clients. Thus, the era of technical specifications and minimization of costs is rapidly coming to an end.

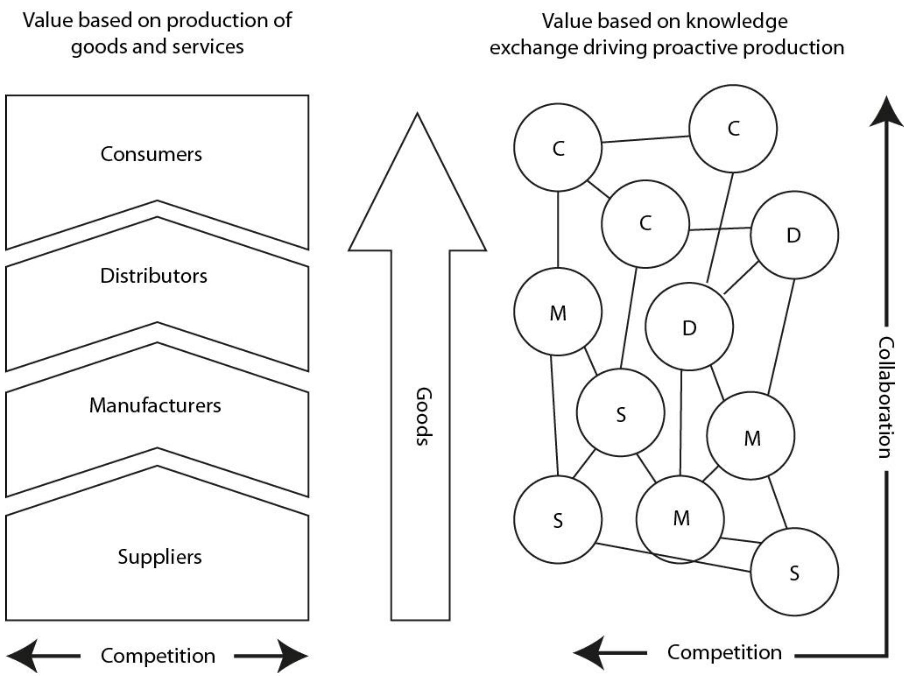

Figure 1: Difference between the value chain and the value network approaches (adapted from Kelly & Marchese, 2015)

Several possibilities exist for improving customer value creation in construction businesses. In addition to advances in brand definition and customer interaction, these possibilities are driven by technological development. The digitalization in general is changing value chains, with large online operators changing businesses. Some specific technologies that may affect construction are also emerging. Additive manufacturing, or as it is sometimes called, 3D printing, is changing the manufacturing industry. The development of construction applications is a topic of much interest. Secondly, the consumerized AR and VR technologies are attracting interest for developing applications also in construction. In addition, the applications of 3D technologies are being enabled by the 3D measuring equipment and UAV´s also being increasingly available for consumers. Together, these technologies may profoundly change the construction industry. In this article, we review these technologies, and present a scenario for future construction, utilizing them. We compare this scenario to the current dominant value chain in construction. Finally, the factors that may prevent the change in the industry are discussed.

2. Current value chain in construction

In order to map the current value chain, it is worth assessing the supply chain in the construction industry, as presented by Vrijhoef and Koskela (2000). Based on their observations of a typical construction supply chain (Figure 2), it is possible to map the corresponding value chain for the same parties (Figure 3).

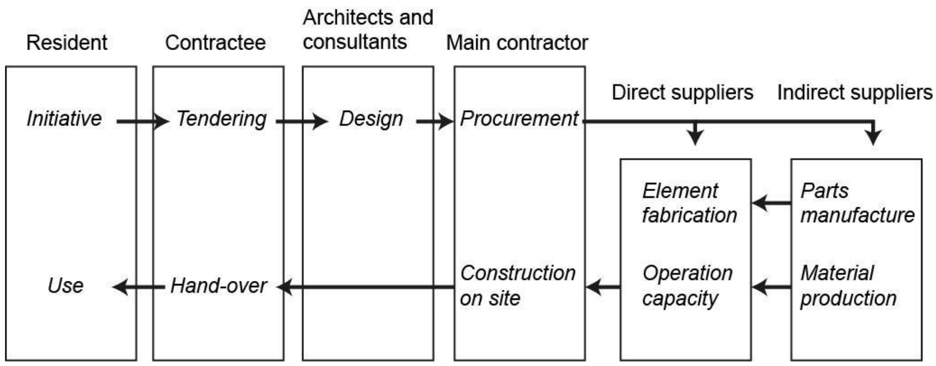

Figure 2: Typical construction supply chain (adapted from Vrijhoef and Koskela, 2000)

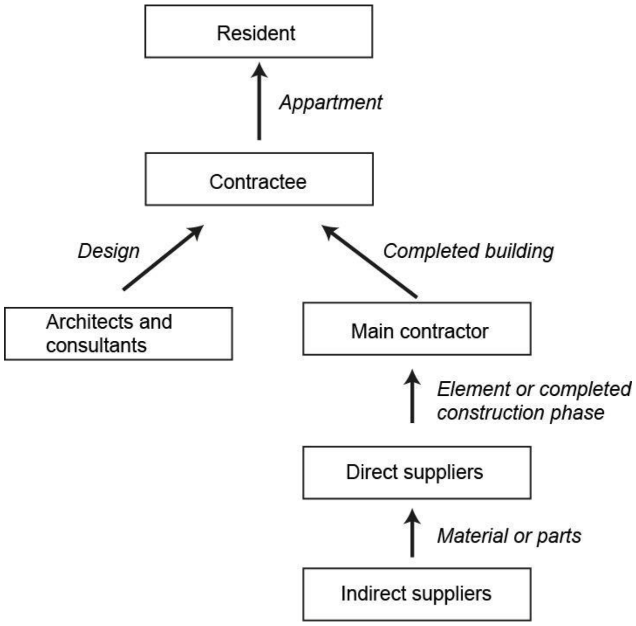

Figure 3: Construction value chain, with the product sold in each step shown in italics.

3. Change agents

3.1 Additive manufacturing technologies

Additive manufacturing (AM) techniques were originally developed as prototyping methods for product development in the manufacturing industry; one particular application being the prototyping of injection molded plastic components. Later on, they have become widely known as 3D printing methods and have spread to several new application areas with the emergence of affordable machinery. At the same time, the technology of 3D printing has advanced while the selection of 'printable' materials has grown (Schubert et al., 2013). In an editorial for the Rapid Prototyping Journal, Campbell, Bourell, and Gibson (2012) summarize the four benefits that are pursued with the adoption of AM technology: customization, improved functionality, reduction of total amount of parts, and aesthetics. As an example of improved functionality, they list a number of features from the aerospace industry that have been attained with AM: integrated mechanical functionality, reduction of required assembly features, and internal features of components (e.g. cooling ducts).

3D printing techniques have also been forecast to revolutionize the construction industry. Some research on this topic has already been conducted (Buswell et al., 2007), and some experimental projects have also been carried out (3DRS, 2015). For example, Lim et al. (2012) reviewed three different AM processes capable of achieving 3D printing with concrete-like materials. The authors estimated the potential advantages of these techniques for construction, and formulated a list of properties: increased freedom of design, reduction in mold costs, and integrated functionality of individual components (e.g. ducts). AM methods may, in future, enable the cost-efficient manufacturing of large, geometrically complex, unique components from materials applicable to construction (e.g. concrete). This could fundamentally change the way in which current buildings are designed using identical, geometrically relatively simple, concrete elements. Therefore, 3D printing technology is highly relevant for the construction industry as it is directly linked to logistics, customization, virtual models, and manufacturing.

3.2 3D measuring

One of the first consumerized 3D measuring methods was the utilization of depth cameras, such as Microsoft Kinect. Depth camera images can be turned into point clouds, and applied in 3D reconstruction (Izadi et al., 2011). Commercial devices intended for indoor measurement are already on market (Matterport, 2015). 3D scanning sensors based on depth camera technology have even been integrated into smart mobile devices (Google, 2015). However, typical issues when using depth cameras are the low measuring range as compared to laser scanning (Falie and Buzuloiu, 2008) and noise in the depth measurements resulting in a limited accuracy (Izadi et al., 2011).

Laser scanning technology has also developed quite rapidly. One of the key development directions is the miniaturization of measuring equipment, price reductions for sensors, and increased ease of use of the measuring instruments. For example, mobile laser scanning (MLS) has reached a point where the entire MLS system can be easily carried by a single person, or flown aboard an UAV (Kukko et al., 2012); currently, systems weighing only a few kilograms have been prototyped.

3D measuring can also be performed using photogrammetry. As computational capacity has increased, the automation of image analysis and 3D reconstruction has become possible. Image-based systems can even be built from quite affordable components (Straub et al., 2015). Applications of these algorithms from consumer camera data sets have also been presented. The process of 3D reconstruction from unordered sets of images consists of, firstly, an estimation of the camera orientations (e.g. Snavely et al., 2006) and, secondly, a dense 3D reconstruction from image pairs (e.g. Hirschmuller, 2008). To enable this, various algorithms exist for fast but dense stereo vision. They have been compared in different contexts, among others, by Sunyoto et al. (2004) and Ahmadabadian et al. (2013).

In addition, other sensor types can also be utilized. For instance, Rosser, Morley and Smith (2015) propose a solution where orientation sensors commonly found in current smart phones are used, together with the device camera acting as a sight, to obtain a coarse outline of a room footprint.

These footprints are then processed together with the house footprint (obtained from survey data) to produce a coarse 2.5D building model. Interestingly, although this solution was based entirely on consumer hardware and commonly available data, it was still able to reach an accuracy of some tens of centimeters.

3.3 Augmented reality

Another technological development with an approaching impact on the construction industry is the utilization of virtual reality (VR) and augmented reality (AR) in creating immersive visualizations of virtual environments. Several projects have already employed AR/VR technology in visualizing BIM models. In this fashion, AR technology will be employed both to visualize 3D models in their future installation site and to help guide the installation activities (Behzadar & Kamat, 2005). Consumer products enabling AR or VR have been released or announced by several companies during the last year, including Samsung Gear VR, Oculus Rift, Sony Morpheus, Google Cardboard, and HTC Vive.

3.4 Multi-sided platforms

The aforementioned value networks are becoming more and more dynamic due to the emergence of multi-sided platforms (MSPs) enabled by digitalization. These platforms typically connect two or more sides of the market via online services, benefiting from the network effects, i.e. the platform becomes more attractive the more it increases its users and complementary service providers. Different from supply chain platforms which feature, for example, mass customization, these platforms act as a foundation upon which external innovators can develop their own complementary products, technologies, or services (Gawer and Cusumano, 2014). Well-known examples of MSPs that have already disrupted traditional industries and their business models include among others, Uber for taxi services, AirBnB for accommodation services, Amazon for retailing, and Apple Pay for banking.

Such MSP operators thrive on data-driven customer intelligence and customer experience, enabled by faster innovation capabilities and greater profits than other industries in general. These ecosystem drivers provide a branded platform for a leading customer experience, offer seamless third-party products and services, and match customer needs with other service providers, extracting “rents” from the business transactions (Weill and Woerner, 2015).

These platforms also generate new end-user services difficult to envision beforehand, enabled by an open innovation ecosystem. Often the platform operators originate from outside the traditional industry players, bringing with them ecosystem business design and a complete customer understanding, thereby disrupting traditional production-oriented business models.

The tools empowering an individual consumer for interior design tasks are already emerging in the software market (Planner 5D, 2015), and it is arguably just a matter of time before these become integrated into the actual purchasing and manufacturing activities.

4. Scenario: future design and construction process

It is possible to combine the techniques of 3D measuring, such as terrestrial laser scanning (TLS) and 3D printing. In so doing, replicas of real world objects can be produced (Virtanen et al., 2014). The combination of 3D printing and 3D measuring opens up significant possibilities for mass customization in the construction industry. By utilizing the 3D measuring tools available in a smart phone, an individual consumer can produce a 3D data set of his or her apartment. The measured data can be further processed, automatically or semi-automatically to produce a 3D model of the measured space. Afterwards, the 3D model can be applied to design components. For example, a space divider can be planned using pre-made parametric models that are then semi-automatically adapted to each individual space, using the 3D model as a reference for measurements. This design process can be achieved by the consumer in an online service. The designed components could thus utilize the possibilities offered by AM. They can include the necessary mounting features, and their internal structure can be optimized to reduce material consumption and maximize strength. The components can then be manufactured using numerically controlled (NC) machines, such as 3D printers. After delivery, the parts would then be assembled on site. As the components are made to measure, the installation time is minimized. This process is illustrated in Figure 4.

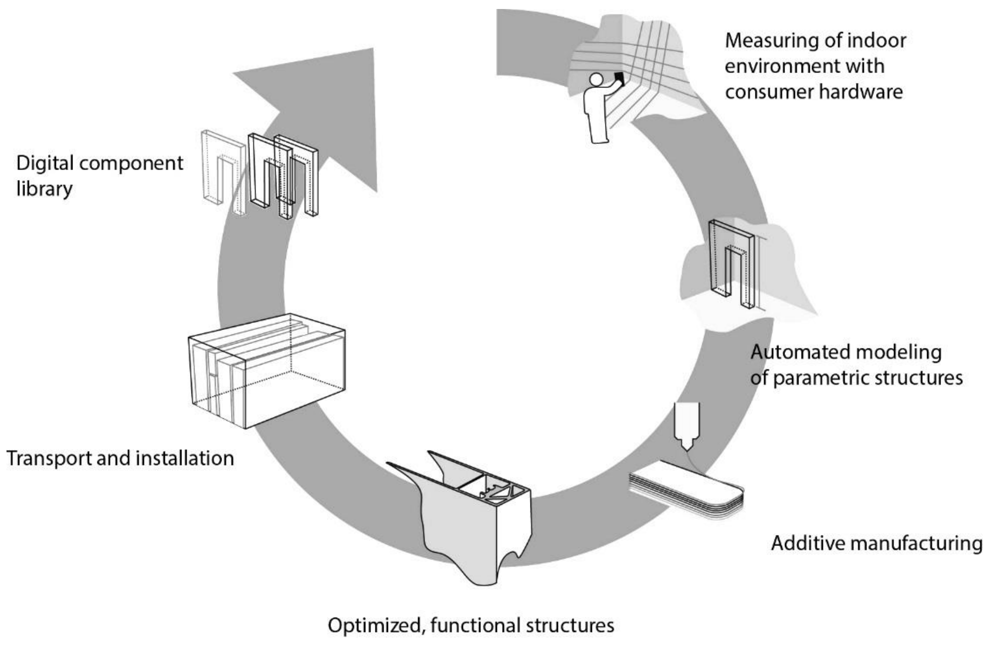

Figure 4: The future design and construction process

5. Discussion

The current value chain in construction is based on suppliers who manufacture individual parts from a single material (e.g. tiles, sheets, and beams) which are then used in manufacturing (e.g. furniture), or modified and installed on site (e.g. construction materials). As the manufacturing of these parts is a traditional industrial process, they are geometrically simple, and there can be a considerable number of these manufacturers. Furthermore, for more complex entities, such as furniture elements, there are direct suppliers (who manufacture furniture) and indirect suppliers (who manufacture materials). In contrast to this, additive manufacturing enables the production of varying, geometrically complex components. As the manufacturing process is tool free, unlike casting methods for example, and is not based on manufacturing the object by removing material from a starting piece as with milling for example, the geometrical variation of parts or complicated geometry does not increase production costs. Therefore, components of varying shapes can be manufactured by the same manufacturer, without using a large amount of pre-made parts. In the most minimalist of situations, the only indirect supplier would be the producer of the printing material. Thus, from a myriad of manufacturers producing geometrically simple objects in longer value chains, manufacturing shifts to a small number of key manufacturers producing complicated objects in a short value chain.

From an economic standpoint, the industry is moving from an incremental increase in value in small steps (manufacturing materials and parts, manufacturing components, and construction on site) to a rapid increase in value in one jump (AM manufacturing of components). The operator controlling the AM manufacturing step has subsequently more control in terms of scheduling and price determination. The amount of excess inventory, logistics, and warehousing are greatly reduced, freeing resources in the process. For the consumer and designer, this shift also increases the amount of customizability. In turn, fewer compromises must be made to adapt the final design to the limited offerings of manufacturers and available components.

An analysis of future value chains in the construction industry is subject to large uncertainties. Making predictions based on technical developments alone is not sufficient, as the construction industry is also affected by other factors, such as regulations that may also change. In addition, the large commercial operators in the field have an influence over the entire system. Finally, it is unrealistic to assume that a single value chain could serve all situations encountered in the construction industry. The supply chain presented in Figure 3 is originally drafted for the development of new projects. Retrofitting a single apartment and construction of a new residential area are inherently projects of a different scale and a different producer-customer relationship. While technological developments will affect both small and large scale construction projects, the resulting value chain configuration may be quite different. Moreover, the value chain presented in this article is clearly more oriented towards renovation operations than the construction of new buildings, which was the focus of Vrijhoef and Koskela (2000).

Like any new process, change takes time, especially in an industry as fragmented as construction. There are several barriers for quick adaptation of the new technologies and radical changes in the value chain. According to Edie et al (2014) the greatest barriers for BIM adoption (in order of importance) are the following: lack of flexibility of organizations, lack of supply chain buy-in, lack of vision of benefits, cost of software, cost of training and lack of technical expertise. Organizations are clearly unsure about their own capabilities and those in their supply chain. Hail et al (2012) highlight the importance of coordination given to the complex nature of construction. They point out the following key barriers of coordination: the nature of construction vary and the same technological methods cannot be used universally, traditional contractual arrangement can prevent to be open for new methods, construction participants may not have a common view, and the approach of construction management may vary between partners. Construction players do not need only new technological tools but also new mental models and management approaches to coordinate their projects towards a more innovative and cost-efficient implementation. Bernstein and Pittman posit - as early as in 2004 – three interrelated barriers for BIM adoption that are still relevant: the need for well-defined transactional business process models, the requirement that digital design data be computable, and the need for well-developed practical strategies for the purposeful exchange of information (Bernstein & Pittman 2004).

6. Conclusions

Additive manufacturing techniques suited for construction are beginning to emerge as commercialized tools. Concurrently, three dimensional (3D) measuring can be performed with laser scanning, scanners utilizing the triangulation principle, or photogrammetry. As these technologies have developed, 3D measuring has become increasingly available to consumers. By studying the current state and development direction of the technology, it becomes more feasible and more likely to forecast the possible value chains of future construction and estimate their impact on the industry.

By combining sensor technology, 3D measuring, AR, VR and 3D printing, the entire chain from planning, measuring to manufacturing and delivery can be digitalized, covering the entire life cycle of the built environment. In future construction, the user should be able to measure the to-be-altered environment with a mobile device, thus producing a digital model to be used in planning. In the planning phase, a new installation, such as fixed furniture, can be assembled from a set of pre-designed modules and individually produced 3D printed components. In this situation, design, visualization, cost estimation, and logistics planning are performed with online systems. After the order is placed, the pieces are manufactured, delivered, and finally installed. Digitalization will push the business models towards data-driven, multi-sided platforms where value-added services and servitization will change the current constellations of value networks.

Smart Water – Intelligent Integration of Information Systems of a Water Utility

Osmo Seppälä[1] and Pentti Janhunen[2]

Finnish Water Utilities Association (FIWA), Finland
Helsinki Region Environmental Services Authority (HSY), Finland
Email: osmo.seppala@vvy.fi

Abstract

The largest water utility in Finland, Helsinki Region Environmental Services Authority (HSY) has started a Smart Water development program. Among many other objectives, this program aims at adopting and extending (1) a standardized data model for water and sewerage networks and (2) a data integration system to enable various ICT systems of HSY – such as the Network Information System (NIS), Customer Information System (CIS), Supervisory Control and Data Acquisition System (SCADA) and Network Investment Management (NIM) – to better interact with each other and also with ICT systems of external partners.

The part of the Smart Water program described here is implemented in cooperation with other large Nordic water utilities and Nordic water utility associations. The plan is to adopt and further develop the network data models developed in Denmark and currently owned by the Danish Water and Wastewater Association (DANVA). The Danish concept of Digital Water Company – Det Digitale Vandselskab (DDV) – has been established by DANVA in order to lift the digitalization and standardization work for water and wastewater networks to a more advanced level, making sure that the ICT strategies, system integrations, data exchanges, workflows etc. are in harmony with the common business processes of the Danish water companies. The aim of this joint Nordic effort is to adopt and further develop the DDV data model into a common Nordic data model applying open data source code and open data model. The ownership, maintenance and intellectual property rights of the Nordic data model should be with public non-profit organizations. The future benefits will be huge for the participating Nordic water utilities, but also for external business actors co-operating with water utilities. For instance, the possibility to share standardized water network data with planning and design consultants, contractors and authorities directly in the digital format can take the water utility sector to the modern Building Information Model (BIM) environment compatible with other infrastructure sectors. This will also open new and innovative business opportunities for commercial ICT service providers. In addition to the participating utilities, such as HSY, the results of the project give other water utilities encouraging examples of innovative developments in knowledge management towards smarter and more intelligent water and sewerage services.

Keywords: *data integration, ICT system, open data model, open source code, smart water, water networks*

1. Introduction

Water supply and sewerage services are invaluable for functioning of the society. Water services and systems are data and information intensive. Vast majority of the water infrastructure is in water and sewerage networks which are buried underground. The huge amount of networks, long life-cycle and a large number of potential information points makes availability and management of data and information related both to physical condition and actual operations of the networks challenging. Sophisticated supervisory control and automation systems are already used to manage network operations better. However, in general the holistic utilization of data related to network operations is not yet very advanced and smart in most water utilities. A common problem is that there is not enough measured data of adequate quality, to facilitate e.g. proper hydraulic or qualitative situation analysis of the network. Electricity utilities in Nordic countries are much more advanced in applying ICT systems in network management than water utilities, but electricity utilities have in most cases applied larger "all-in-one" ICT systems instead of integrating several decentralized systems.

The aim of this paper is to introduce recent and ongoing developments of intelligent ICT-applications of Helsinki Region Environmental Services Authority (HSY) in water and wastewater network management. HSY has started an ambitious Smart Water development program, which covers several key areas of its operations. Among many other objectives, this project aims at adopting and further expanding to Finnish utilities (1) a standardized data model for water and sewerage networks (location and properties, condition, hydraulic and quality data) based on the Danish experiences, and (2) a data integration system to enable various ICT systems of HSY – such as the Network Information System (NIS), Customer Information System (CIS), Supervisory Control and Data Acquisition System (SCADA) and Network Investment Management (NIM) – to interact better with each other and also with ICT systems of external partners such as consultants, contractors and authorities. The aim of this project is also to show examples and encourage other Finnish water utilities to advance and improve their water related ICT systems towards more intelligent and holistic management systems. HSY is in the Finnish context a very large water utility compared to all other utilities. On one hand its novel and innovative approaches would be important in paving the way for future utility management practices for other utilities, but on the other hand this "size polarization" is challenging for functioning markets. However, due to their size HSY and other largest Nordic water utilities together can also have a positive impact on the market behaviour within the ICT systems supplier market.

2. HSY's Smart Water program

2.1 HSY and its water and wastewater systems and their management

Helsinki Region Environmental Services Authority (HSY) is the largest water and wastewater operator utility in Finland and one of the largest in Nordic countries. HSY produces water and sewerage services to about 1 million people in Espoo, Helsinki, Kauniainen and Vantaa cities.

HSY's water and sewerage section has about 430 employees and its annual turnover is about 230 million euros.

The length of HSY's water distribution network is about 3 000 kilometres and wastewater sewerage network about 2 800 kilometres. In addition there are storm-water sewers for about 2 200 kilometres. There are altogether 12 elevated water towers, 32 booster pumping stations, about 520 wastewater pumping stations and 52 storm-water pumping stations, 3 water treatment plants and 2 wastewater treatment plants. Total value of the water infrastructure assets is at least 1.6 billion euros.

HSY uses Network Information System (NIS) to manage information related to its water distribution and sewerage networks. There is one master system in use, which is complemented by several other GIS systems for specific uses. In addition to Network Information System, HSY uses a number of other ICT applications in its operations. These include for instance Supervisory Control and Data Acquisition System (SCADA), Customer Information System (CIS), Financial Information System (FIS), Business Intelligence Software (BIS) and several authority level ICT systems. Most of these applications are currently operated more or less as isolated applications with not much compatibility or integration between each other. Knowing the enormous amount of data and information collected and utilised in a large water utility, this situation is definitely seen as a challenge and inefficient utilisation of resources.

2.2 Overall scope of the Smart Water program

HSY's Smart Water program consists of several sub-projects, such as:

1) HSY's open piloting platform for business-based product development
2) Intelligent measuring devices in water and wastewater networks
3) New condition assessment technologies for water and wastewater networks
4) Integration of water services related and other ICT systems (e.g. Financial Information System)

Business companies are given the opportunity in the Smart Water program to pilot their innovations and products in real-life situations in HSY's water services systems, including physical network infrastructure and data related to systems. The first sub-project aims at creating principles and opportunities for implementing these pilot projects. Pilot installations will be done in co-operation between HSY and the participating companies. Results will be available for both HSY and the companies.

The second sub-project aims at developing intelligent measuring devices or probes to measure key parameters available in water and wastewater networks, focusing on pressure, flow and acoustic parameters related to leakages. Measured data is used e.g. to establish real-time situational view of the network operations, thus supporting decision-making especially in exceptional situations. Data also helps in understanding the complex operation of water distribution and sewerage systems and in improving customer service. Initial findings suggest utilisation of probes based on membrane technologies (MEMS).

The third sub-project aims at developing methodologies and technologies to assess structural condition of water distribution network and for CCTV inspections of sewerage pipes. Knowing the huge total length (about 5 000 km) of HSY's wastewater and storm-water sewerage networks, the aim of establishing a holistic view of the network based on measured data sets rather challenging requirements for the assessment methods. The focus will be on developing interpretation methods for sewer inspections, based e.g. on machine vision interpretation of CCTV or laser scanning material.

The fourth sub-project on integration of HSY's water services related ICT systems is the main topic of this paper and is discussed in more details in the following chapters.

2.3 Integration of HSY's water services related ICT systems

The main objective of this sub-project is to develop an efficient, generic data integration system in order to facilitate data transfer and two-ways interaction between the existing ICT applications. The ICT systems in use by the water services are among others:

- Water distribution control system, SCADA
- Remote operation and control system for wastewater pumping stations
- Systems for customer information, customer relations and communication
- Systems for network information and network investment management
- Hydraulic modelling applications (water, wastewater and storm-water networks)
- Regional spatial data information system
- Financial Information System (FIS), Business Intelligence System (BIS)

The leading idea of the sub-project is to utilise the abundant, high quality measured and validated data from the utility's various processes and to integrate the ICT systems through well-functioning data exchange and integration between systems. Thus, the central element is the data integration system. Each data item should have one data storage location in the master data system. Copying data items to other satellite ICT systems and possible further data refinement is done in the master system, but updating can be done in satellite systems.

Figure 1 illustrates the basic concept of the data integration system in the water utility's ICT application system. ICT systems (System 1-n) are used e.g. to control water and wastewater networks, to manage network or customer information, to hydraulic modelling, to manage investments, or to create situation view for managers. Data to any ICT system from another system will be exchanged using a centralised data integration system. Additional systems can be added easily ("plug-and-play"). The concept also has a service interface for external ICT systems used e.g. by consultants, contractors, administrative bodies, etc. These will be controlled through access code systems. The concept as such is based on the principle of open data model.

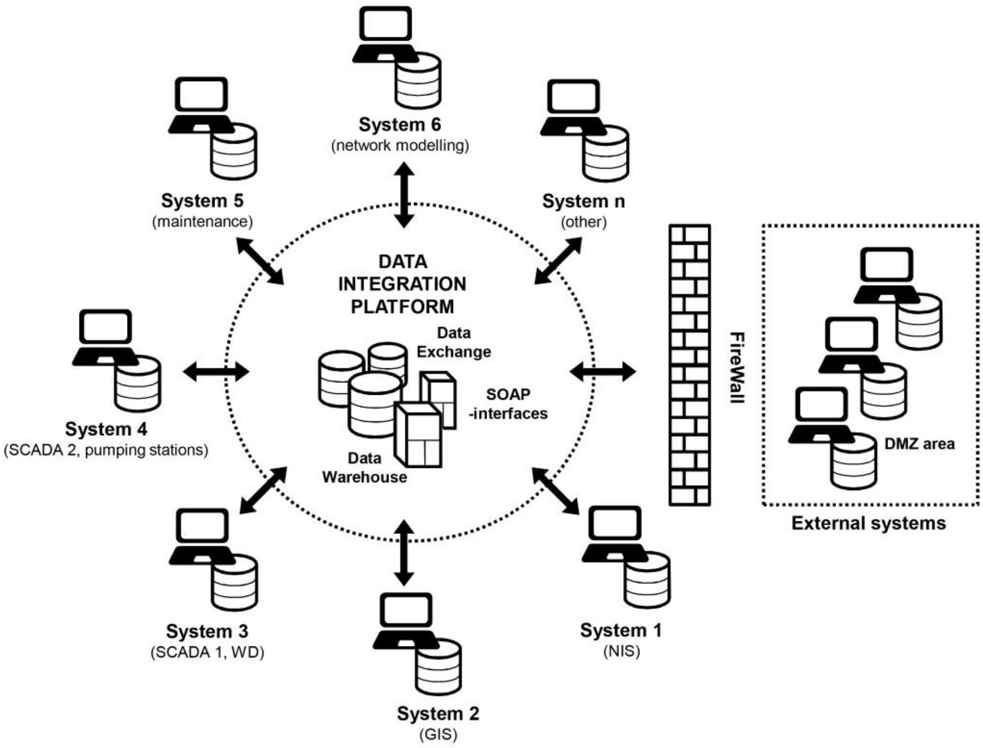

Figure 1: The principal idea of data integration system in HSY's water services related ICT architecture (Janhunen, 2015).

Benefits of integration of different ICT systems include:

- No need to manually transfer or feed data from one system to another, which reduces work, and errors and speeds up data management
- Makes it possible to choose for each purpose an ICT application which suits best from technological and functional point
- Makes it possible to develop applications flexibly and provides opportunities for software suppliers of different sizes. New (small) agile software suppliers can provide specific ICT programs for specific purposes.
- ICT programs can be renewed or procured flexibly by modules.
- Data can be updated to a master database from other applications.
- Data can be further refined during integration and transfer.
- Risks related to the use of only one software supplier ("vendor lock") can be minimised. Vendor lock easily increases total costs and makes product development too rigid.

3. Development of the network data models

HSY has started discussions and plans to adopt and further apply for its network management operations a data model developed in Denmark for the Danish water and wastewater sector. The

Danish Water and Wastewater Association (DANVA) has developed a concept called the Digital Water Company (in Danish Det Digitale Vandselskab, DDV). DDV as such was established in 2011 in order to lift the digitalisation and standardisation work in the Danish water industry to an advanced level, ensuring that e.g. ICT-strategies, system integration, data exchange, workflow etc. in in harmony with the common business processes in the Danish water companies (Asmussen, 2012). This is in line with the Danish government's strategy together with the local authorities for enhancement of digitalisation 2011-2015.

The Digital Water Company (DDV) is a co-operation project between Danish water companies and the Danish Water and Wastewater Association (DANVA). DDV focuses on guidelines and best practices for increased alignment between business processes and data. The four main tracks of DDV are: (1) digitalisation and change management, (2) standardisation in the water industry, (3) external standardisation and co-ordination, and (4) customer focus and customer trends. Standardisation within DDV includes e.g. terminology and data models, data quality, accessibility and reuse, interface descriptions and data exchange. In external standardisation e.g. the requirements coming from the INSPIRE directive are taken into account.

Already in 2004 DANVA developed a data model for registration of wastewater pipes called DANDAS, followed in 2005 by a data model for registration of water pipes (DANVAND). In 2008 a model was added for data model maintenance purposes (D&V). The principles of data models concur with Service Oriented Architecture (SOA) and are in line with the requirements of the INSPIRE directive. Figure 2 shows the linkage between different data models within DANVA's DDV concept.

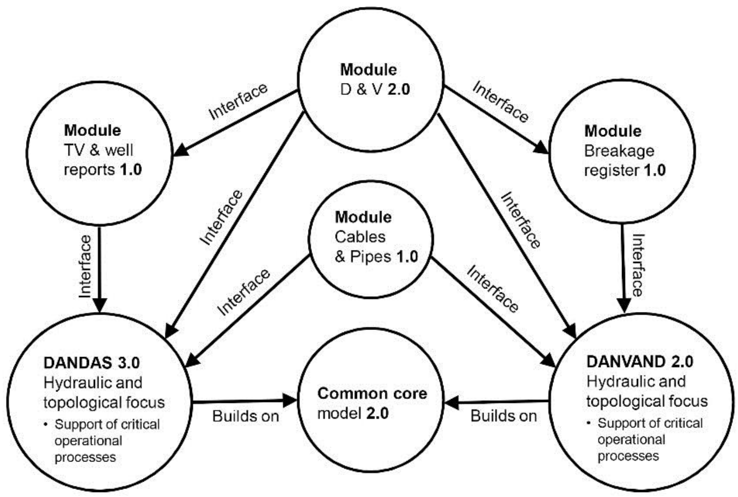

Figure 2: DANVA's data models and their interconnections (Gadegaard 2015).

Network data models (DANVAND and DANDAS) include a standardised description for water and wastewater networks and their components. Example of the structure of the data models is shown in Figure 3.

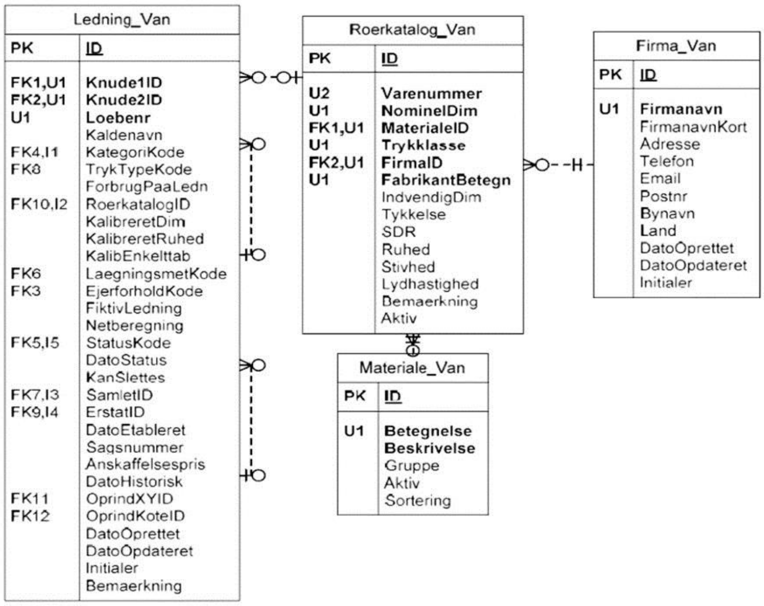

Figure 3: Example of a partial structure of DANVA's data model (Asmussen 2012).

In 2015 some of the largest water and wastewater utilities and national water and wastewater utility associations in Denmark, Sweden and Finland commenced negotiations and plans for adopting and applying the Danish DDV-concept also in Sweden and Finland. All the Nordic so-called “6-city water utilities” are involved in these negotiations.

One of the main reasons for HSY in applying the DDV-concept in Finland is the need to adopt a data integration system to enable compatible and integrated use of data and information in a standardised format between the various ICT-applications in use. The basic model needs to be extended for this purpose. Extending the Danish open data models to other Nordic countries also requires that in each country a competent and neutral body will be identified and engaged to administer and coordinate the use and maintenance of data models. Water utilities adopting data models in their operations should be prepared to finance the costs of administration and coordination.

There are several commercial data integration ICT-applications available on the market, for instance those developed by Oracle, Microsoft, Napcon and others (Seppälä 2015). There are, however, some concerns in HSY for using fully commercial data integration applications. Adoption and development of such fully commercial data integration software would lead to a continuous and deep market dependence from the software supplier. Another important point is that a non-commercial data integration system could easily be replicated to other water utilities in a much more affordable manner than a fully commercial system. Examples of non-commercial data integration systems include e.g. Mule, Geoserver, and PostGIS database. An ideal situation would be a combination of non-commercial and commercial systems for instance on a 50/50 basis. An illustration of a commercial generic data integration system is shown in Figure 4.

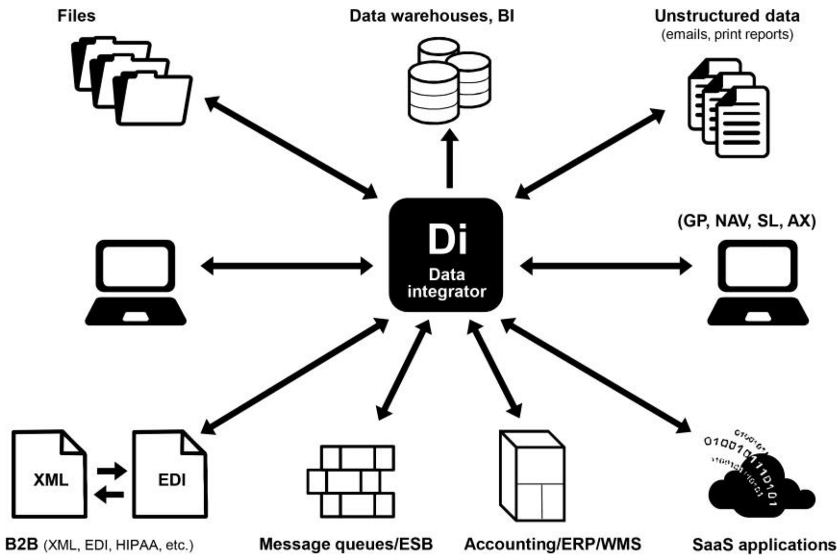

Figure 4: Schematic example of a commercial generic data integration system (Seppälä 2015).

HSY has good and practical reasons for its policy of finding a balance between non-commercial and commercial ICT systems. HSY has already fallen into a vendor lock situation regarding some of its ICT systems, which has caused excessive development and maintenance costs and inadequate interest from the supplier's side for further product development.

The trend towards open data systems and advanced data exchange between systems is in the long run a win-win situation for both system end-users and system suppliers. For end-users the main benefits are faster product development and improved quality when data is exchanged easier and without errors between data systems. ICT system suppliers need to review their revenue logic in future, because customers will increasingly shift from one-supplier closed systems more towards open data source and open data exchange systems. The new paradigm benefits more new and innovative system suppliers, but also traditional closed system suppliers may expand their business if they are agile enough to renew their business strategy.

4. Discussion and Conclusions

HSY as a large water and wastewater utility has a dire need to establish smart and well-coordinated system of collecting and utilising data from its operational and managerial data systems. As part of a larger Smart Water development program, HSY intends to improve its utilisation of high quality measured data from its water and sewerage systems through extensive and advanced ICT system development.

Instead of entering into a massive one-supplier system, HSY wishes to build its system on the existing decentralised ICT systems which are integrated through a data integration system. Moreover, the plan is to develop a non-commercial data integrator instead of using generic commercial data integrators. However, as a whole HSY intends to apply a balanced combination of non-commercial and commercial ICT systems for its operations. This will also ensure a healthier market situation and avoid the one-supplier vendor lock situation.

Adoption and local tailoring of data models developed in Denmark for the water industry has been identified in HSY as a priority solution to achieve functioning integration of ICT systems, being essential part of HSY's Smart Water project. HSY works in co-operation with the Nordic 6-city group water utilities to develop national applications of the Danish DDV model. Discussions between the Nordic water utilities and associations are ongoing, but the actual implementation of the Nordic expansion of the Danish DDV model has not yet been started. Besides the participating Nordic water utilities, there is need to organise administration and maintenance of locally tailored data models in each participating country.

HSY's aim is also to show examples and encourage other smaller Finnish water utilities to advance and improve their water related ICT systems towards more intelligent and holistic management systems. This is one reason why a non-commercial data model and data integration system has been chosen as the basis for development. This makes it easier for other Finnish and other Nordic water utilities to affordably start using the data models and integration system compared to fully commercial systems. Wider deployment of these non-commercial systems could also have a positive impact on the ICT supplier market in the Nordic countries.

In addition to HSY's internal benefits of integrating its own ICT systems, another key result is the possibility to share standardized water network data with planning and design consultants, contractors and authorities directly in the digital format can take the water utility sector to the modern Building Information Model (BIM) environment compatible with other infrastructure sectors. This will also open new and innovative business opportunities for commercial ICT service providers.

Abstract

While the UK Government's 2016 BIM mandate could filter through construction supply chains and touch even the smallest organisations, respondents to recent surveys have questioned the ability of industry to upskill and respond to the challenges encapsulated in digitisation (Knutt, 2015). As Small and Medium Enterprises (SME) and micro-firms form the majority of UK construction organisations, the adoption of BIM by SMEs is a vitally important factor in delivering on aspirations to digitise the UK construction sector. Implementing innovation within SMEs is complex and a non-linear process, suffering from scarce resources, lack of skills and systematic measurements, which can result in implementation failure and frustration for SME managers. (McAdam et al., 2010) Based on literature review and data gathering from industry experience, this paper will scope out and identify key challenges faced by BIM 4SME in reaching out to a fragmented construction sector. Driven by strategic objectives, UK construction is faced with embedding digital working into whole life supply chain activities. Perceived barriers may include cultural issues, the embodiment of industry step change, engagement with disruptive technologies and the ability of SMEs/micro SMEs to embed innovation into status quo work practices and forward planning. (Christensen, 2000; Vanheverbeke, 2012). The purpose of the research is to develop an evidence based and representative perspective on where UK construction SME/micro SMEs sit as a key industry group in responding to UK Government's mandate for digitisation.

Keywords: BIM, SMEs/micro-SMEs, reach, knowledge transfer, assimilation

1. BIM 4SME; genesis and paradigms for change

According to Government figures, construction contributes almost £90 billion gross value (GVA) added to the UK economy representing almost 6.7% of total output and sustaining 280,000 companies. (Anon., 2008) It has been argued that the UK construction industry is highly fragmented, (Egan, 1998) (Pringle, 2012), both by international standards and in comparison with other domestic sectors. Over 90% of organisations in the built environment sector employ less than 10 workers, and almost 72,000 firms are one-person operations. Fewer than 130 construction organisations have a workforce of 600 or more. It has been noted that these large firms generate only around 25% of the industry's output by value. Supporting professional and technical services are similarly diverse. Even the largest UK construction company commands only a 3.5% share of the market; this would not even place it within the world's top 20 construction organisations.

During 2011, the UK Government's Construction Strategy was published. (Cabinet Office, 2011). The report announced the Government's intention to require collaborative 3D BIM (with all project and asset information, documentation and data being digital) on its centrally funded projects by 2016. In effect, UK Government embarked on a four year programme for sector modernisation with the key objectives of: reducing capital cost and the carbon burden from built environment construction/operation by 20%. Pivotal to realising these ambitions was the adoption of information rich Building Information Modelling (BIM) technologies and processes which it was perceived would unlock new more efficient ways of working for construction to facilitate realisation of strategic industry targets.

The BIM Task Group established a number of working groups (including the so called "BIM4s") to take its message to UK construction. BIM 4SME is a pan-discipline industry group with a specific remit to interact with the UK's SME and micro-SME construction communities. Membership draws from a range of professional and industry representative interests. Since 2012 BIM 4SME has developed its remit to:

- Raise awareness of BIM within the SME marketplace
- Ensure SMEs understand the requirements of Level 2 BIM relevant to their role in the supply chain
- Demonstrate the value proposition / business benefits to the SME: better efficiency, better information and better decision making
- Make sure the SMEs understand the risks of doing nothing with regards BIM implementation
- Help SMEs get ready for the Level 2 switch over: where they are and what next?
- Produce simple guidance around the BIM process in simple English and to match business needs

While realisation of UK Government objectives for digital working is predicated on wholescale buy-in by the construction sector, at November 2015, there were no reliable indicators in place to record industry's state of readiness to deliver on the 2016 BIM mandate. The authors would argue that without appropriate indicators, it is impossible to predict whether or not the Government's ambitions for digitisation of construction are deliverable.

To date, BIM 4SME has relied on volunteer effort to disseminate its messages framed around perceived benefits of adopting open and collaborative BIM. The group hosts a website specifically targeted towards SME/micro organisations and BIM 4SME's Linkedin page has stimulated online discussion and debate. (For example, in a recent post, the UK Government's 20% cost saving target has been challenged) In addition to the framing and application of BIM standards, protocols and the like, the authors would argue that upskilling of the construction sector needs to be informed by evidence based critique from stakeholders.

Since 2014, BIM 4SME has run a series of BIM clinics for practitioners, contractors, sub-contractors and suppliers. Although BIM 4SME could be described as a "push" organisation, its developing knowledge base relies primarily on interactions with SME practitioners and industry organisations. In that context, BIM 4SMEs mission could be interpreted as bridging between *evangelical* (UK Government protocols) and *evolutionary* (developmental industry models) approaches to BIM uptake (Kouider and Paterson, 2014).

2. Research Methodology

2.1 Research Aim and Objectives

The authors' hypothesis suggests that as we approach the end of 2015, UK Government's aspirations for the digitisation of the construction sector may not be matched by industry's ability to deliver. The aim of this research is to benchmark the state of readiness among SMEs/micro-SMEs in addressing UK Government's 2016 BIM mandate. Following a literature review, data gathering will take a representative slice through construction supply chain organisations to identify skill/knowledge gaps. The investigation will also attempt to determine how the challenges of BIM adoption by SMEs could best be addressed at strategic industry level to facilitate delivery on key targets such as cost saving and carbon reduction.

The objectives of the research are:

1. Review construction SME statistics from the literature and identify perceived challenges to engagement with BIM in the UK.
2. Scope out perceived barriers to BIM adoption within SMEs.
3. Identify key challenges for the BIM 4SME group in reaching out to a fragmented industry struggling to address the need to embed digital working into design, construction and supporting supply chain activities.
4. Make evidence based recommendations to strategic UK construction organisations on how challenges inhibiting the digitisation of construction could be overcome.
5. To enhance the capability of BIM4SME as an industry organisation in providing effective support to facilitate SME engagement with BIM.

2.2 Research Strategy

The phenomenon of this research is contemporary, socially constructed and may change over time. Thus, epistemologically subjective with presupposed interpretive approach of the social phenomena, focusing on the details of situation and the subjective meaning of the motivation of the social actors, aligned with the interpretivism and in opposition with positivism theoretical perspective of research (Saunders, 2012).

The research adopts a multimethod qualitative methodology, investigating in depth small samples to obtain rich and deep data to be analysed. Themes and patterns will be identified using an inductive approach ranging from the specific to the general. The objective is to create a conceptual framework for analysis through cross-sectional sampling of SME/micro built environment organisations.

The methods adopted are literature review, data gathering from case studies provided by BIM 4SME organisations, interviews of BIM4SME experts, and observations from BIM Clinics. BIM Clinics involve SME firms approaching industry experts to discuss company experiences and concerns with BIM; a significant opportunity to observe interactions between the BIM 4SME organisation and SME practitioners. Finally, in broadening the sample from BIM 4SME contacts, the research will capture data from interviews with SMEs practitioners to increase the scope of perceived barriers and key challenges with BIM adoption.

All data trawled from the research will be systematically reviewed using content analyses: describing, connecting and classifying data through the identification of patterns emerged from the data (Gray,2004).

3. Literature Review

3.1 SMEs in the UK Construction Industry

More than 90% of the UK construction sector comprises the small, medium sized and micro organisations (SMEs) described by the European Commission as the “engine room of the European economy” (EC, 2013). Small and Medium Enterprises (SME) is usually defined by companies with less than 250 employees. In addition, for capital allowance purposes in the UK, SMEs would have turnover of less than £22.8 million and a balance sheet of less than £11.4 million pounds (HMRC, 2011). In 2015, there were 5.4 million SMEs in the UK, accounting for 99% of the UK business and 48% of the country turnover {Rhodes, 2015, Business Statistics}. Moreover, SMEs can be divided into 3 groups:

- Micro companies – 0-9 employees
- Small Companies – 10-49 employees
- Medium Companies – 50-249 employees

The construction sector enterprises accounts for 18% of the UK all business, but only 8% of employment and 7% of turnover. The reason for that is the large amount of micro companies in construction, boost the overall number of companies, but not the number of employed in the construction sector (Rhodes, 2015).

Although the official construction statistics cannot offer exact figures for SME numbers and turnover, they do highlight the importance of SMEs to the UK construction industry. Due to the classification adopted in the Official Construction Statistics (2015), if considering firms within the range from 0-114 number of employees, (therefore excluding medium sized companies with 115-249 employees) SMEs represent 96% of all firms in the construction sector, accounting for 61% of total value of work in the UK construction. These figures would be likely to rise if medium sized enterprises in the range of 115-249 employees were included in the overall range.

3.2 SME BIM adoption

BIM awareness is growing in the UK, according to recent survey published at NBS National BIM Report (2015), 95% of respondents were aware of BIM, and 48% are currently using BIM in their organisations. That is a significant increase in the use of BIM from 2010, which was a small 13% of respondents using BIM, but it also demonstrate that despite evidence of awareness, the majority of construction enterprises have not yet engaged with BIM. In the authors' view, lack of clear definition as to what "BIM" means, could be a significant qualification to meaningful interpretation of the statistics.

International surveys demonstrate that large companies are leading the way into the uptake of BIM. For example, the Smart Market Report (2014) stated that 34% of the large firms reported more than 5 years' experience with BIM, while half of this amount (16%) of small firms would have the same experience. However, it is not clear how the report categorised company sizes labelled as "large" and/or "small". NBS (2014) survey reported awareness and use of BIM by size of firm, comparing firms with 1-5 employees and firms with more than 6 employees, as Figure 1 shows. This survey confirms that small companies are behind large companies in the engagement with BIM. "large" and/or "small". NBS (2014) survey reported awareness and use of BIM by size of firm, comparing firms with 1-5 employees and firms with more than 6 employees, as Figure 1 shows. This survey confirms that small companies are behind large companies in the engagement with BIM.

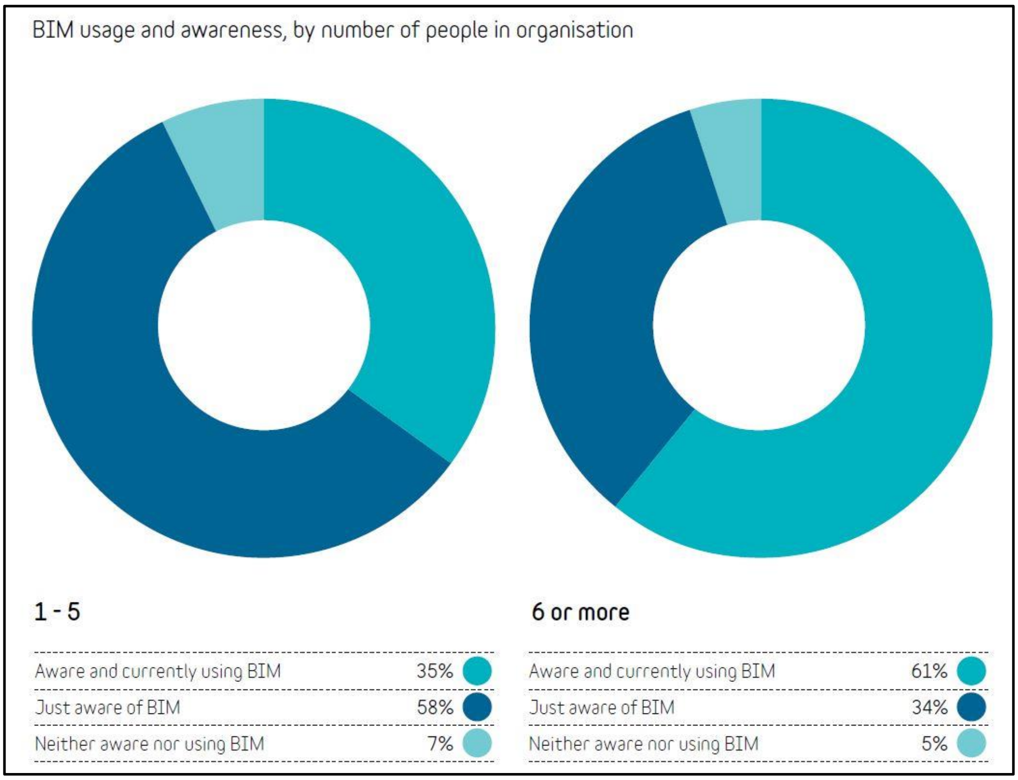

Figure 1: BIM Usage and awareness, by number of people in organisation. Extract from NBS National BIM Report, after NBS (2014)

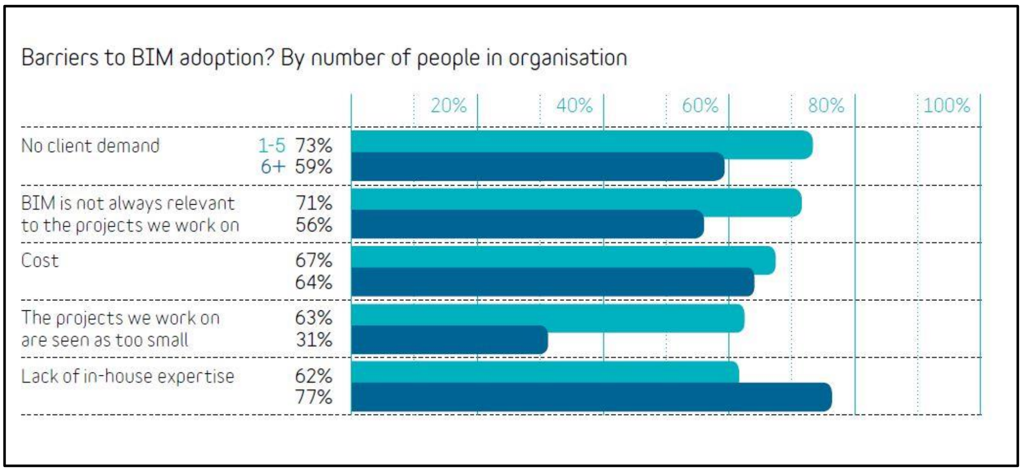

Figure 2: Barriers for BIM adoption, by number of people in organization. Extract from NBS National BIM Report, after NBS (2014)

When asked about the barriers for BIM adoption the lack of client demand is the most important reason for companies with 1-5 employees, while for companies with more than 6 employees the lack of in-house expertise is highlighted as the principal barrier, as Fig.2 above demonstrates.

Because collectively SMEs represent a majority stakeholder in the UK construction sector, their engagement with BIM is crucial for the realisation of UK Government's 2016 mandate. This preliminary research suggests that there is a lack of detailed information about micro, small and medium companies BIM adoption in the UK and a lack of evidence based data about the challenges and barriers which SMEs face when migrating to digital working; specifically BIM adoption.

3.3 Challenges and Opportunities

The authors would argue that embodying BIM into construction SME business models is likely to involve disruption to status quo work practices and workflows. Unlike manufacturing industry, the construction sector faces the challenge that every building is different, "a unique prototype, developed by a team of consultants, contractors and other suppliers that may never have worked together before and may never work together again." (Anon., 2015)

Also BIM involves engagement with new technologies, step change because of the ways in which information is embedded in data rich models and the use of unfamiliar protocols, for example the IFC format for file exchange. Harvard Business School professor Clayton M. Christensen coined the term *disruptive technology*. Christensen (1997) separated new technology into two categories: sustaining and disruptive. Sustaining technology relies on incremental improvements to an already established technology. Disruptive technology lacks refinement, often has performance problems because it is new, appeals to a limited audience, and may not yet have a proven fit with some organisations' business models.

Christensen pointed out that large organisations are designed to work with sustaining technologies. They excel at knowing their market, staying close to their customers, and having a mechanism in place to develop existing technology. Conversely, they have trouble capitalising on the potential efficiencies, cost-savings, or new marketing opportunities created by low-margin disruptive technologies. Christensen noted that it was not unusual for a large organisation to dismiss the value of a disruptive technology because it does not reinforce existing company goals. On the other hand, due to their adaptability and structure flexibility, SMEs are more likely to engage with radical innovations, which have the potential to generate high financial returns (Adegoke et al, 2007).

In the UK, there is a commercial pressure to implement BIM with the Government mandating BIM use on public project and non-public clients demanding BIM at tender stages. In some large organisations as Skanska, Laing O'Rourke, Arup, and HOK, BIM may be part of a company's strategy for innovation and engineering excellence. Across large industry organisations, CEOs and strategists have acknowledged BIM as a potential driver to improve efficiency and increase profits. BIM may be mandated for all new company contracts and services (Jordan and Jeffrey, 2013) Considering that large organisations rely on supply chains (including SMEs) to deliver their projects, these companies could be pushing the uptake of BIM by small and medium sized firms.

It has been argued that, in the future, engagement with BIM may influence the awarding of contracts/sub-contracts and consequently a significant opportunity for SMEs to win business. As highlighted by UK Government spokesperson Chloe Smith, during her 2013 presentation to the BIM4SME group: "As an SME, no matter what your role in the built environment is, it is highly likely your business will or should be involved in the BIM process whether through supplying or managing data." Smith argued that SME BIM engagement could be either be via a publicly funded project, or as part of contractual requirements from a supply chain partner (Platts and Eynon, 2013).

SMEs with appropriate BIM expertise could have a commercial advantage when engaging with projects managed by BIM enabled main contractors. In addition to single contract relationships, SMEs could also benefit from repeated business and long-term relationship with established and new supply chain partners. Another opportunity for SMEs is the possibility to tailor their input to a "just-in-time" methodology to reduce risks of abortive work, re-work and errors. For example, by using a main contractor's digital site model, a steel sub-contractor could design and detail assemblies to fit with site constraints and/or simulate site handling logistics. Historically, sub-contractors may engage late in the design/construction processes with heightened risk of abortive work and on-costs. BIM can potentially offer unseen benefits for a range of supply chain partners, particularly sub-contractors and suppliers.

A further opportunity is for SMEs to develop new BIM related products and services for commercialisation in national/international AECO markets. While BIM transforms the way the industry works, new products and process are going to be demanded by the industry. Being at the forefront of innovation can bring a competitive advantage. Innovation is essential for firms' competitiveness, survival and growth. It can drive competitive advantage, improve productivity and enable companies to capture higher value components of the value chain.

The construction contracting industry in particular is perceived to have low levels of innovation, (measured by research and development) compared with other sectors. Although expenditure on wider innovation such as design and organisational innovation is between two to three times larger than industry's expenditure on tangible assets such as machinery and tools, (£7.42 billion versus £3.15 billion in 2007) the proportion of firms innovating still ranks low relative to other sectors. A literature review carried by UK Government Department of Business Information and Skills highlighted several reasons for the apparent low levels of innovation in construction: (i) high level of industry fragmentation and limited collaboration; (ii) procurement impacting on the level of collaboration; (iii) sub-optimal knowledge transfer and lost learning points; (iv) issues around market uptake and awareness of benefits from innovation; and (v) access to finance and risk-averse attitude to innovation (BIS, 2013).

The literature suggests that SMEs are receptive to engagement with disruptive technologies. SME and micro organisations tend to be structurally lean, agile and potentially adaptable to innovation. However, industry surveys suggest that large companies are leading the way on BIM adoption. This research found that some large contractors may have reached significant levels of BIM maturity in the UK and internationally. Paradoxically, it is small and medium companies which constitute the majority by numbers of the UK's construction sector. In fact, in terms of construction supply chain characteristics, main contractors may manage the projects but sub-contractors/suppliers, (mostly SMEs), which actually do the work. For example, the literature has suggested that, for example, on a £25 million contract, the smallest sub-contract could be as little as £10k. Therefore, it is crucial to understand factors which impact on SME engagement with BIM. As a strategic issue, the adoption of BIM by SMEs is critical for the UK construction industry to achieve high levels of expertise and engagement with digital working. Also at operational level, to achieve alignment with short/medium term Government targets.

4. Preliminary Findings

4.1 Drawing from the BIM4SME Experience

Tables 1.2 outlines a range of perceived challenges to step change in work practices based on industry/practitioner data gathered and collated by BIM 4SME team between September 2012 and March 2013. These parameters were factored into BIM 4SME's launch in London in April 2013. In articulating possible challenges/barriers, the intention was to stimulate discussion among focus groups at the launch event. Also to scope out priority areas for forward planning and testing by data gathering, analysis and the framing of appropriate recommendations as outlined earlier in the paper. Perceived challenges were structured at strategic (industry) and operational (organisation) levels. There may well be interdependencies between factors identified at strategic/operational levels. That premise will be tested during Phase 2 of the research between January and March 2016 through further data gathering from SME organisations.

Strategic challenges
• Lack of objective advice and critique within the industry
• BIMUK forward plan for education/training, FE/HE, industry etc
• Are national BIM surveys carried out to date representative
• Lack of R+D culture in UK construction. (historical + contemporary)
• Fiercely competitive market situation suggests favours those with knowledge
• Fast moving pace of technological change
• Downstream dissemination of UK Government strategy is a volunteer effort
• Lack of clear and achievable protocols, eg common templates for construction of BIM models
• Unclear legal framework (are risks perceived or real)
• Parallel information flows on BIM from professional, regulatory, statutory bodies (PSRBs)

Table 1: BIM and strategic industry challenges

Operational challenges
• Cost of tooling up and risks of redundancy of software/hardware
• Training costs
• BIM wash blurs consistency of message
• BIM overload syndrome. Associated anti-BIM backlash particularly from micro-
• Lack of familiarity with BIM language/concepts eg "soft landings"
• Weakest link in the chain eg only one project team actor BIM compliant
• Variable levels of client engagement with BIM. Do clients perceive added value
• How robust is data embedded in and exchanged between models, eg thermal modelling, cost data etc
• Risks of uncertainty/abortive work related to organisations engaging with BIM on live projects while still way down the learning curve
• Lack of exemplars from BIM users on small projects,. Little evidence to back up claims of collaborative working in 3D environment other than on large projects.

Table 2: BIM and operational challenges for SMEs/microSMEs

5. Conclusions

Following the publication of the 2011 UK Government Construction Strategy, the industry has witnessed an increase in the awareness and use of BIM. In addition, industry groups became established to offer support and guidance to construction enterprises. BIM 4 SME is part of the BIM Task Group which aims to facilitate the transition from conventional to digital working in micro, small and medium enterprises.

The literature has demonstrated that most construction sector employment comes from SMEs, which are companies with up to 250 employees and up to £ 11.4 million turnover. In the UK construction, Industry SMEs represents the hugely majority of construction firms, accounting for more than 61% of the total value of work in the sector. Despite the recognised adaptability of SMEs with respect to innovation, the paradigm shift to digital working in construction is currently being led by large organisations. Preliminary findings from BIM 4SME industry workshops held between September 2012 and April 2013 identified a number of challenges to BIM uptake; these were classified at strategic and operational levels. The next phase of the research will test perceived challenges by sampling from a representative cross-section of construction SMEs. The summative part of the study (Phase 2) aims to make recommendations to the industry groups that are supporting SMEs in their BIM journeys. To date, the research has highlighted not only challenges, but market opportunities for SMEs and BIM.

Traditionally, the UK construction sector is risk averse. Construction's fragmented morphology combined with the unique nature of building projects tends to mitigate against change. Even when collaborative approaches to working prove successful, it is difficult to maintain significant levels of continuity over time. On the other hand, BIM technologies and digital processes are seen as motivational factors which could bring improvements to industry performance. The next stage of the research will also expand on the analyses of key challenges for BIM 4SME in reaching out to SMEs faced with embedding digital working into design, construction and supporting supply chain activities. Drawing from industry data gathered and taking an evidence based approached, the concluding phase of the study will propose ways to overcome perceived challenges and provide continuing support to SMEs in engaging with BIM. Realising high level objectives for digitising UK construction (cost and carbon reduction) must take account of industry's capability to deliver.

Abstract

Any construction project is full of risks, which if not minimized or eliminated can jeopardise its outcome. The sources of risks vary from project to project. With refurbishment projects, information is scarce leading to making assumptions about them, which generally entail risks. On the other hand, very new and very large projects are complex involving many disciplines and generating too much information in the different phases of construction life cycle. Actions by stakeholders in the different phases related to the project information have implications on quality, cost and schedule-related risks. Building Information Modelling (BIM) has been hailed as a solution to many challenges in construction including risk management. Applications of BIM in quantity surveying, project planning, facilities management and sustainability have been extensively researched and now common in the scientific literature. However, research about risk management in a BIM-enabled environment is still very sketchy. This is compounded by the plethora of BIM software systems which overwhelm end-users to be able to make informed decisions about their uses in risk management. The work presented in this paper is the first step of a more comprehensive research aimed at improving the understanding of risk management in a BIM environment. The focus of the investigation is about the potential of and limitations of 4D BIM software systems in managing construction risks. A purely desk-top study has been adopted to achieve the aim of this study.

Keywords: BIM, construction, efficiency, nD modelling, risk

1. Introduction

Similar to most projects, construction projects are highly subjected to risks. This is further exacerbated by their complexities, dynamism and peculiar nature (Rostami *et al.*, 2015; Taillandier *et al.*, 2015). Rostami *et al.* (2015) argued that construction projects are subjected to more risks and uncertainties because of the varying range of activities and transformation involved from the planning stage to completion. Such activities include complex planning procedure, regularly bespoke and time-consuming design as well as costly production processes. Furthermore, construction projects are becoming increasingly larger and more complex in physical size and cost. If not effectively managed, the risk associated to this huge size can lead to losses (Chen *et al*, 2012). Also, projects are based on teamwork with different interested stakeholders, and the co-operation among them is formed around extensive, disparate and interrelated processes. People are very unpredictable in behaviour, compounded by unpredictable external environmental risk factors in delivering projects can be very high. Construction projects involve a lot of decision-making with consequences on the project's success or failure (in terms of cost, time and quality) and on its environment (Taillandier *et al.* 2015). Sawhney *et al.* (2014) argued that construction is confronted by challenges such as time and cost overruns, wastage, low levels of standardisation, fragmentation, inconsistent procurement practices and low use of technology. Studies by Abderisak and Lindahl (2015) revealed that cost and time overruns are quite common with increases in the range of 50-100% being more regular and an increase of over 100% is not an unusual case. The risk associated with cost and time overruns will have immense effects on the outcome of any project if not properly managed.

Digitization of construction using BIM offers innovative ways to effectively manage construction risks (Hartmann *et al*, 2012; Tomek and Petr, 2014). Mott MacDonald, a management, engineering and development consultancy, defines BIM as "a coordinated set of processes, supported by technology that adds value through creating, managing and sharing the properties of an asset throughout its lifecycle (Mott MacDonald, 2015)." In order to support BIM workflow of processes, a market for BIM technologies has significantly grown in recent years. Although the growth of BIM software is great, its huge number and other technical issues have posed challenges for end-users. Lee and Sexton (2007) argued that there is a lack of holistic information for relevant construction parties regarding the characteristics of the various software packages and their appropriate uses. Furthermore, issues of non-compatibility (interoperability) among software packages are still too common. Day (2011) argued that depending on the software put to use, BIM models get very large in file size as the level of detail increases and this poses problems to computers with limited memory sizes. Fazli *et al* (2014) claimed that one of the major weaknesses is getting different file formats to function properly when creating a combined building information model. When data is taken from the original BIM model, a certain value is attained and when converted into another file format, a different value can be generated. A recent study by Abanda *et al.* (2015) led to the identification of/and differences between 122 BIM software systems across different construction domains. However, the study was top level with lack of details on specific domains. Building on Abanda *et al.* (2015), this study aims to conduct a detail investigation of BIM risk management software systems with focus on interoperability amongst the different software systems. Three main objectives employed to achieve the objectives of this study are: an Investigation into why construction risk management is required; the identification of the various commonly used scheduling and 4D BIM software for construction risk management; an investigation into the interoperability amongst the scheduling and 4D BIM software systems.

To facilitate understanding, the remainder of this paper is divided into 4 sections. In section 2, the methods used to achieve the aim of this study are examined. To provide the context of this study, in section 3, risk management in construction is explored. This is followed by an assessment of the traditional scheduling and 4D BIM software systems, where emphases was placed on the type of operating systems supporting the software, the import/export file formats of the software and whether risk has been integrated into the software. In section 4, the key findings and how the study objectives have been achieved are discussed. The paper concludes by a way of summary in section 5.

2. Research methods

Given that the core of this study is based on interoperability, its definition is important to provide a context for the adopted research method. Generally four types of interoperability exist in the literature. These are syntactic, technical, semantic and organisation interoperability (Rezaei *et al*., 2014). For purposes of this study, the focus is on syntactic interoperability which refers to the ability of two (or more) separate systems or software programmes to communicate and exchange data (or information) with each other and use the data (or information) that has been exchanged (Rezaei *et al.*, 2014; Bahar *et al.*, 2013). With this definition in mind, four criteria for the different software to be reviewed were established. The first criterion considers whether the software can be installed on two most popular operating systems, i.e. Mac and Windows. The second was based on how legacy scheduling/risk management tools were integrated into 4D BIM tools. By integration we mean the ease with which 4D BIM can read into legacy scheduling and/or risk management tools. The third criterion is about the file exchange formats inbuilt into the software system. The last criterion is about whether risk is integrated as part of the scheduling or 4D BIM software systems. These criteria are captured in the framework shown by Figure 1.

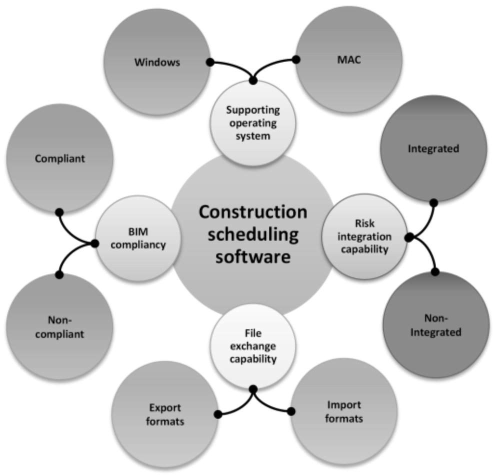

Figure 1: Factors qualifying the potential of construction scheduling software

Based on Figure 1, an extensive literature review from peer-reviewed sources and vendors' websites was conducted. Giving the emerging nature of BIM, peer-reviewed studies about BIM software are scarce and the few existing studies have tapped information from vendors' websites (e.g. Crawley et al. (2008) and Abanda et al. (2015)). In examining the vendors' websites, the specification documents were explored to identify the different operating systems, file exchange formats supported by the different software systems, whether scheduling and/or risk software was integrated in 4D BIM software systems and finally, whether risk has been integrated in the software. To further gain clarity about the set criteria for this investigation, some of the software were installed and explored. That led to the identification and inclusion of 34 project scheduling, 3 legacy risk management software and 20 4D BIM software systems.

3. Risk management and its digitization in construction

Risk management involves creating uncertainty awareness, qualifying the risks, managing the controllable risks and curtailing uncontrollable risks impact by risk allocation/appointment (Liu *et al*, 2007). There are many definitions of risk management, all portraying the fundamental goal of minimizing the impact of risk. According to Irimia-Dieguez *et al.* (2014), risk management is the systematic process of identifying, analysing and responding to project risk. Also, Tohidi (2011) defined risk management as the process of identifying and assessing risk, and applying methods to reduce it to an acceptable extent. Hence, risk management involves the process of determining the likelihood of risk to occur, taking necessary steps to examine its effects and fashioning out ways to prevent or lessen the effects, in the event that it occurs. Generally, managing projects revolves around the proper management of the delivery of project objectives in terms of time (scheduling), cost, quality and safety as most risks emanate from them. The focus of this study is on risk associated with construction project scheduling. In emerging BIM paradigm, 4D stands for scheduling in a BIM tool. As such the discussion ensuing in this section concerns the applications of risk management in traditional software systems and contemporary risk management approaches in BIM enabled environments.

3.1 Risk management in traditional scheduling software

Project scheduling is important for construction project managers as it facilitates their task of tracking and managing the triple constraints of time, cost and quality of projects (Faghihi *et al.*, 2014). Planning and scheduling in construction normally involves activity sequencing in space and time, taking into account other construction processes like procurement, resources, spatial constraints, etc. Traditionally, bar charts (Gantt charts) are used to schedule construction activities but these methods have been unable to show how or why certain activities are linked in a given sequence (Eastman *et al.,* 2011). Once these schedules are created, there appears to be no direct link between the computer-aided-design (CAD) drawings and the construction schedule. As the design progresses in typical project scenarios, the construction manager reviews any updated drawings, then updates the schedule to reflect these design changes where such clarification depends on the accuracy of the construction manager (Hardin, 2009). Eastman *et al.* (2011) further argued that the spatial components aren't adequately captured by the traditional methods and nor are they linked to the building model. Further claims were that scheduling (using the traditional methods) is manually intensive and often at times does not concur with the design thereby creating complications for project stakeholders to understand the schedule and its impacts on site logistics. Two most common software systems used in traditional scheduling are MS Project and Primavera. It is important to note that traditional software has been in existence for ages even before the advent of BIM and/or 4D BIM modelling. While some traditional scheduling software systems have compatible plug-ins with 4D BIM, others do not. Also some have integrated BIM while others have not. A summary of the different project scheduling software uncovered are presented in Table 1.

Table 1: An overview of construction scheduling software systems

Software	*BIM compliant*	*Export file format*	*Import file format*	*Risk analysis integration*	*Operating system*
Asta Powerproject	*Yes*	*HTML, CSV, MPX, XML, XER*	*PDB, MPX, XML, XER, DIR, STX*	*Yes*	*Windows/Mac*
ConceptDraw PROJECT	*No*	*XML, MMAP CDPZ, CDPX, CDPTZ, CDMZ, TXT,*	*CDPZ, CDPX, CDPTZ, CDMZ, TXT, MMAP, XML, MPP, MPT, MPX, XLSX*	*No*	*Windows/Mac*
Deltek Open Plan	*No*	*XML, CSV*	*XER*	*Yes*	*Windows/Mac*
Express Project	*No*	*Express Project files*	*Express Project files, CSV*	*No*	*Windows/Mac*
Fast Track Schedule	*No*	*HTML, MPX, XML, ICS, MMAP*	*MPP, MPT, XML, MPX*	*No*	*Windows/Mac*
Gantt Project	*No*	*CSV, MPX, XML, HTML, PDF, GAN,*	*CSV, ICS, TXT, XML, GAN*	*No*	*Windows/Mac*
MicroPlanner X-Pert	*No*	*TXT, DIF, CSV, XML*	*TXT, DIF, CSV, XML, MPX*	*No*	*Windows/Mac*
MS Project	*Yes*	*XML, MPT, MPP, CSV, TXT, XLS*	*MPP, MPX, XML, MPT, XLS, XLSX, XLSB, XLSM, CSV, TXT*	*Yes (2010 and later versions)*	*Windows/Mac*

3.2 Risk management in 4D BIM software systems

Sebastian (2011) argued that BIM is not the same as the widely known computer aided design (CAD) because it goes beyond generating the traditional digital (2D or 3D) drawings. It is an integrated model in which all process and product information is combined, stored, elaborated and interactively distributed to all relevant project actors. Also, the proposed design and engineering solutions can be assessed against the client's requirements and expected building performance using BIM. The use of BIM during the construction phase can support good communication network between the building site, the factory and the design office (Sebastian, 2011). Fazli *et al.* (2014) also argued that communication processes that exist between stakeholders in a project can be enhanced massively through BIM. This is in contrast to traditional projects in which building visualizations (views) are made from scratch while BIM-based projects, the visualizations can be made from previously created models and can be monitored real-time. The schedule of construction is directly linked to the 3D model, enhancing visualization of the sequential construction or sequence activities of the building, thus allowing schedulers to visually plan and communicate activities in the context of space and time (Eastman *et al.*, 2011). Furthermore, Hartmann *et al.* (2012) discussed that project risks are communicated as a risk inventory using Gantt charts and sketches that however, do not allow project managers to completely visualize and understand risks, their location on site and their implications on project deliverables making it hard to collaboratively examine and mitigate project risks. The argument was that 4D models capture both the temporal and spatial aspects of schedules and communicate schedules more effectively than Gantt charts. In the experimental study carried out by Reizgevičius *et al.* (2013), they argued that 4D models can shorten construction time by 1/3. Furthermore, they claimed that the use of 4D CAD model can reduce mistakes to a greater extent (twice as much) in construction processes and help in detecting and removing them more quickly. In Hartmann *et al.* (2012), a case study showed that if time schedule is aligned well with existing risk management processes, design teams can use 4D models to visualize project risks in time and space. Mahalingam *et al.* (2010) discussed that 4D CAD are beneficial in the planning and construction stage where in the former, it will be useful in communicating the construction plans and processes to clients who can then visualize the project and convey their suggestions, approval or disapproval. In the construction stage, it will be particularly useful in comparing the constructability of work methods visually in order to detect conflicts or clashes. It also serves as a visual tool for contractors, clients, subcontractors and vendors to review and plan projects' progress. The summary of the 4D BIM software uncovered in this study are presented in Table 2. Even if many 4D software deal implicitly with many aspect of risk management (logistics, space, etc.), the risk analysis integration considered here is the explicit feature included in the software. It is important to note that some of the software systems are also 5D BIM systems, i.e. 3D plus cost dimension.

Table 2: An overview of 4D BIM software systems

Software	*Export formats*	*Import formats*	*Risk analysis*	*Operating*
Autodesk Navisworks	*3D DWF, DWFx, FBX, KML, NWD, NWF*	*TXT, ASC, DGN, PRP, PRW, DWF, DWFx, W2D, DWG, DXF, FBX, IFC, RVT, SKP, NWD, NWF, NWC*	*No*	*Windows*

4. Findings and discussion

Tables 1 and 2 provide an overview of some scheduling and 4D BIM software systems and how they integrate with BIM. The software systems were classified according to the different criteria set in section 2. A summary of how the research objectives were achieved will be discussed.

Table 3: How the research objectives were achieved

To investigate why construction risk management is required;
This was achieved through a literature review and discussed in sections 1 and 3. In section 1, the rationale for risk management in construction projects was examined. Then in section 3, the rationale and benefits for digitising risk management were discussed.
To identify the various commonly used scheduling and 4D BIM software for construction risk management;
This was achieved through an extensive literature review. Peer-reviewed and vendors' websites served as source of information. The findings from this review were presented in Tables 1 and 2.
To investigate the interoperability amongst the scheduling and 4D BIM software systems;
Once the software systems were identified, the specification manuals were read to determine the software characteristics (e.g. file import and export format). Furthermore, in some cases some of the software had to be installed and explored to determine whether it is compliant with BIM, types of file exchange formats and whether it contains risk components.

By achieving the objectives, four main findings were uncovered. Firstly, some traditional construction scheduling software are BIM compliant and also contain a risk analysis component. For example, Asta PowerProject has a risk component, and its project can be read by 4D BIM software system (e.g. Synchro). Secondly, most traditional scheduling software are not yet integrated in BIM and do not contain a component for analysing risk in construction (e.g. Project Xpert and Rational Plan Professional). Thirdly, some 4D BIM software systems have a risk analysis component (e.g. Synchro and Vico) while others do not (e.g. Navisworks). The last is that some scheduling and 4D BIM software systems can be installed on Mac and/or Windows operating systems. The findings from this study can be modelled using a Venn diagramme (Figure 2) which reveals the relationship between the different software systems.

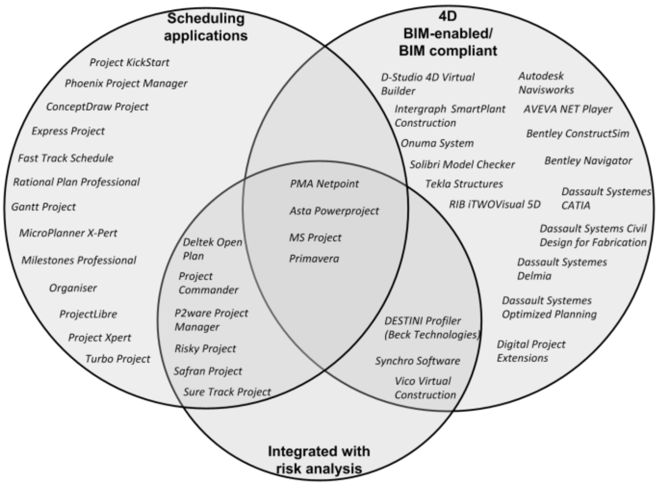

Figure 2: Software category summary

5. Conclusions

With construction projects increasingly becoming larger and more complex, there is the need for efficiency in the way construction activities are carried out. The construction industry is known for its inefficiencies, and amongst many, scheduling (time) risk is not left out. This study has explored the domain of risk management through which an understanding of the various problems that give rise to risks in construction projects was achieved. Consequently, some of the available traditional scheduling software systems were examined based on their compliance with BIM. However, it was clear that these software systems are not quite efficient in specifically managing scheduling risk. With the global advancement in technology, BIM has emerged as a technology capable of bringing more efficiency in the way the industry operates. It is in this regard that a critical appraisal of 4D BIM software systems was carried out. Although, BIM is still in its early phases, one of the benefits of BIM is that it can further enhance better risk management through 4D modelling. Through 4D modelling, project managers can be able to visualize the virtual construction of any project, identify any risk associated and make more subjective decisions rather than objective decisions. The traditional software systems are not capable of doing so but with 4D software systems, this is possible. This has been illustrated through the different literatures in this paper as well as the critical appraisal of some of the 4D software systems presented. Nonetheless, this study has not investigated how schedule risk management can be performed in a BIM environment. Future studies will focus on the processes of undertaking schedule risk management in a BIM environment for proper understanding of how to manage risk using BIM.

Facilities management

Visualization of Facilities Management KPIs during Early Design Using BIM

Francisco Forns-Samso[1], Tuomas Laine[1] and Marie Geissler[2]

Abstract

The use of building information modelling (BIM) in Facilities Management (FM) is a central topic of study in the construction industry at the moment. Most of the current research in the subject is focused on using BIM to efficiently deliver handover building information, support maintenance activities and close the loop in the building lifecycle. However, the use of BIM opens another set of opportunities for FM professionals that can help them to be part of a more integrated design process. This paper studies the involvement of FM professionals during the early design phase supported by the use of BIM tools. BIM tools are capable of simulating and predicting different parameters that can be utilized by FM professionals and later be used as FM key performance indicators (KPIs) to support their decision making process. In addition, the paper presents the Multi KPI visualization tool that enables the compilation of simulation results related to energy, cost and sustainability. By using the Multi KPI tool, a facility manager is able to influence in an integrated design process which opens a new set of innovative opportunities for the FM field that can positively impact the building lifecycle.

Keywords: facility management, building information modelling, key performance indicators, early design, KPI visualization

1. Introduction

During the last decade building information modelling (BIM), lean practices and integrated project delivery methods have been the major drivers of innovation in the architecture, engineering and construction (AEC) industry. With the increasing complexity of building projects and increasing number of unknowns, the combined use of these three methods has allowed for making more accurate predictions that can meet the client requirements, cost, schedule and quality of the project (Khanzode et al., 2007). After experiencing the benefits during design and construction, the project owners are also interested in extending the benefits of BIM in facilities management (FM) and possibly cover the building lifecycle. BIM for FM has been a topic of discussion for several decades, but in practice the implementation in FM is still in an early phase without yet being as successful as in design and construction. A range of potential applications of BIM in different areas of FM have been proposed in the literature such as for operation and maintenance (O&M), asset management, space management, performance management and as a building information database (Forns-Samso et. al., 2015). However, the implementation in these areas bring along organizational, technological and process issues that need further investigation. In addition, research in this area is predicated on the premise that facility managers are only involved in the operational phase limiting different approaches on how BIM can be a useful tool for facility managers. Additionally, a thorough description of the FM industry has been constantly overlooked or mainly focused on operational activities and neglecting the value input facility managers can bring in supporting strategic level decisions in the design phase.

2. Literature Review

2.1 Facilities Management

Facilities management is said to cover all aspects of property, space, environmental control, health and safety, and support services, and it requires that appropriate control points are established in the organizations (Alexander, 2013). As a young discipline, the FM business field developing rapidly and continuously (Elmualin et al., 2010). In the past FM was often regarded as merely a sub-profession such as maintenance, caretaking, or cleaning of buildings or it was considered as a secondary discipline of principal professions in the categories of real estate, engineering, architecture and construction (Atkin, 2009). The current trends indicate that FM will be moving from operational to strategic because of its potential to in creating value for business activities (Meng and Warren, 2015). As such, the participation of FM professionals is growing, evolving and not only active in the post construction phases but also in the early phases of design.

Barrett and Owen (1993) divide FM into operational and management functions as two broad categories by function analysis. *Operational* functions are the daily or routine support functions involving workers. Activities at this level have a regularly short-term scope, and involve specific processes, simple and straightforward, such as repairing, replacing, cleaning, refurbishing, etc. Traditionally, operational functions were performed by in-house departments in educational and healthcare facilities but they had to be multifunctional and the personnel had to be multi skilled. Currently, it is more common that non-core business activities are outsourced to external specialists who can provide effective and efficient services (Meng and Warren, 2015).

Management functions can be distinguished at tactical and strategic levels. Tactics are action plans involving managerial operations for specific and routine activities (Johnson et al., 2008). Such activities are for example, safety procedures for prevention or proper use, maintenance plans and care of maintenance resources. Activities on this level support responsible behaviour in the workplace and the continuity of working conditions. At the strategic level there is consultation and non-routine planning aimed at making the best, long-term use of the organization’s physical resources and overall facilities. Johnson et al. (2008) see management strategy as dealing with the complexities of ambiguous, non-routine situations which can affect the direction and future of the whole organization. Strategic decisions demand an integrated approach since the entire organization should move in the same development direction. Strategy is needed to cope with the prospect of an unknown and changing future. Although long term forecasting can only hypothesize about the future, strategic planning aims to reduce uncertainty by choosing a preferred path and a reasonable long term direction for the development of the organization.

2.2 BIM for FM

The research in the area of BIM for FM has increased rapidly in the last years. A recent literature reviews by Forns-Samso et al., (2015) summarizes the potential BIM uses in different functions of facilities management. The area with stronger focus is in supporting maintenance activities in building operations. Such potential uses include visualization and location of building components with access to real time information concerning attribute data and historical maintenance information. It also facilitates the scheduling of maintenance tasks and the ability to virtually develop a maintenance program without need of making a site visit. However, all of such uses depend on the accuracy, consistency and reliability of the data.

The second category with stronger focus is information management. Information management deals with improving data management during the lifecycle, handover information, as-built/as-maintained model used for the operational phase. Articles in this category investigate about interoperability, information exchange standards such COBie, IFC, FMie etc. and data management procedures. The vision in this research area is geared towards a lifecycle information management approach by capturing information from initial phases of the project through demolition. Major concerns with this implementation are towards the processes and roles for data capturing and data maintenance during the building lifecycle. Supportive concepts are used from industries such as manufacturing, automobile, and shipping with a strong focus on product lifecycle management (PLM). In addition, the literature considers emerging requirements for the capture of Building Performance Attribute Data.

The third category is the use of BIM for building performance which is mostly concerned with tracking and monitoring energy consumption, thermal performance, and components performance. Based on the literature building performance can be measured by integrating other systems such as requirements management, energy simulations tools and building automation systems.

The fourth category is in the area of asset management which is strongly related to maintenance activities but are more closely related to tactical decisions such as assessing the service life of components, maintenance programs, historical data and predictions about equipment failures and replacements. The area of asset management seems to have wider publications from Australia and UK.

The fifth area is space management which is concerned with activities related to real estate functions and cost. Publication numbers in this area are the lowest but it could be because already sophisticated systems such as Computer Aided Facility Management (CAFM) or

Integrated Workplace Management Systems (IWMS) have been widely used in the area of space management and BIM has not found a distinctive application from what already exists.

As described BIM for FM has many potential applications. However, there are only a few studies that show potential uses of BIM for FM in the early phases of design and how to support strategic level decision in FM. With that premise the current study gives a perspective how BIM can be utilized by FM professional in the early phases of design.

2.3 Early involvement of FM expertise during design

The involvement of FM professionals during early design phases is perceived of high value for entire facility lifecycle. Jaunzens et al., (2001) produced a guide that includes the participation of the facilities management team that is part of a client organisation in the design of future facilities and how the FM team´s position within the client organisation, its level of expertise and relationship with the design team affect this participation. In this study, they were able to identify issues relevant to facilities management which should be stated in the design brief, namely maintenance, flexibility and adaptability and the environmental policy.

Jensen (2009) proposed a typology of four mechanisms for knowledge transfer, to establish an integration of building operation considerations in building design. Jensen's mechanisms of knowledge transfer are the following: (1) Utilizing building operation experiences to create codified knowledge, increasing designers' awareness as a result, (2) Boosting the skills and capabilities of facilities managers, increasing designers' awareness as a result; (3) Using power to guarantee that designers seriously take into consideration building operation issues through facilities management participation; (4) Using power to guarantee that design teams seriously utilize codified knowledge.

Wang et al (2013) proposed a framework with the use of BIM to engage facility managers in the early design stages. The main activities improved were in space planning, energy analysis and maintenance planning. Using BIM as a source of information proved to be valuable for collaboration and reduction of life cycle costs. Enoma (2005) states that FM involvement at the design stage will add value to the facility by "ensuring less 'rework', emphasising value for money, efficient control of the supply chain and team work". However, the main barriers of FM involvement are the increased cost in with their participation and when the client is not the end-user of the building.

2.4 Key Performance Indicators

KPIs have become progressively more established within several industries as a performance measurement system. The advantages of using KPIs in facilities management is to direct the managerial effort towards more important areas of performance, and can be embedded in the FM services contract to clearly present the required outcomes and their relevant monitoring and control. It is important that KPIs are relevant, measurable or quantifiable in order to make appropriate comparisons (Lavy et al., 2014). The majority of KPIs generated in FM are the ones related to the cost of maintenance and operation, revenue, space management, and environmental and safety issues.

KPIs have become a part of growing area of analytics, a field that deals with prescriptive analysis. Prescriptive means that decisions regarding how to improve the performance of a facility are made based on data analysis. It utilizes the process of optimization to identify the best solution. In other words, it prescribes how to achieve the best outcome considering the effects of variability. This is recommendation phase where decision and support are coupled with expert opinions to create tactical and strategic guidance for the organization. The process of data analysis may be performed using actual or simulated data that is based on reasonable assumptions. In summary, the process of analytics can be effectively used with simulated data to analyse the relationships and impacts of KPIs.

Within this context the analysis of different KPIs using simulated data can be beneficial for facility managers during the early design phases to support their strategic level decisions. Different BIM platforms are able to assess the facilities lifecycle performance using simulations such as ECOTECT, TRNSYS, RIUSKA etc. However, they are not extensively used by facility managers because, as explained previously, relevant FM KPIs contain a wide range of parameters that cannot be interpreted by a single simulation platform. Therefore, it is needed a platform that can visualize a different set of parameters derived from different applications. This research try to cover that gap by presenting the Multi KPI tool described in the next section.

3. Research Goals and Objectives

To widen the scope in the use of BIM for FM, its implementation should not only focus in facility managers supporting operational activities but also involve them actively in early design phases where FM professionals can provide valuable input in the decision making process, add value in the facility design and lead to a more integrated design process.

The goal of this study is to propose a platform that compiles dynamic simulation results from different BIM platforms and present the simulation outputs as Key Performance Indicators (KPIs). KPIs can be visualized and analysed by facility managers to improve the decision making process. KPIs can be for instance, total energy consumption, CO_2 emissions, total cost of energy consumption, investment cost, maintenance cost. The following are the specific objectives for this study:

(1) Widen the scope of BIM for FM to be used in the early phases of design

(2) Employ different simulated KPI outputs useful for Facilities Management

(3) Visualize and analyse the relationship between input variables and KPIs using a sensitivity analysis and uncertainty analysis

(4) Demonstrate using visualization techniques the generations of different scenarios and supported decision making

4. Research Methodology

This project uses design science methodology. The use of BIM for FM has been widely discussed in the last years without achieving tangible benefits. Within this context, design science research is an accepted problem-solution finding method that it is suitable for this study. Design science would mean designing a framework/tool as an artefact that would help the construction industry but essentially facility managers make use of BIM and support their decision making process. Vaishnavi and Kuechler (2004) described a model of the general process followed by design science research and its multiplicity of as practice variants.

The process for design science research contains different steps and the expected outcomes from each step: (i) *Awareness of the problem* which uses different sources to find an interesting problem in an industry or a reference discipline. The outcome is the proposal, formal or informal, for new research effort. (ii) *Suggestion* is the following step from the proposal, it is an essential creative step where a new functionality is envisioned or enhanced from an existing one. (iii) *Development* which focuses on the novelty of the artefact being developed and does not necessarily be construction of an artefact but design of it. (iv) *Evaluation* is where the artefact is evaluated according to the criteria explicitly explained in the proposal. Deviations from expectation, both qualitative and quantitate, are carefully noted and must be explained. It also contains an analytic sub-phase where hypothesis are made about the behaviour of the artefact. (v) *Conclusion* is the end of the research cycle and final stage of the research effort. The result concludes with the deviations of the behaviour of the artefact from the revised hypothetical revisions. It places a great emphasis on the knowledge contribution in the area of research.

In this project we focus on the suggestion-development phase where the artefact is envisioned or partially created as part of the development phase.

5. Multi KPI Decision Support Tool

The development of Multi-KP is intended to support multidisciplinary work and enhance collaboration between projects teams. Also, it should support the facility manager, owner, decision maker, in analyzing the impacts of key performance indicators. The Multi-KPI tool helps teams to work in a more structured way but enabling flexibility and interaction in the analysis of alternatives facilitating the decision making process. Multi KPI tool uses concepts in the development of decision support systems (DDS) tools in information systems. As such, the Multi-KPI should function as a critical tool for the rapid comparison of different evaluation criteria that could support facility managers. Therefore, Multi KPI should help the complex decision making process, assist in evaluating alternative options or scenarios, deal with complexity and have a clear, reproducible procedure. The Multi-KPI is developed as a web-based decision making application that uses a graphical multi-attribute utility analysis to evaluate and compare alternatives based on key performance indicators.

5.1 Energy Simulation

Simulation modelling has been usually used for the facility´s energy performance. Augenbroe (2002) stated simulation modelling is now being more widely applied in post-construction phases such as commissioning and facility management. In fact, simulation has become an integral part of the whole building design, engineering and operation process. In this project we use energy simulation platform RIUSKA to obtain the different Key Performance Indicators related to energy consumption and CO2 emissions.

5.2 Cost Simulation

Lifecycle cost analysis is used to evaluate the economic feasibility based on the calculation of the equivalent values of all the important costs that occur within the life span, with particular focus on buildings or the major components of buildings. An LCCA is conducted using the following four steps. (i) The analysis target is identified, which is the first step toward making a cost-effective decision by creating and evaluating the alternatives that can meet the minimum performance standards. (ii) The basic assumptions are established for the LCCA, including the analysis period and discount rate. In addition, the initial investment cost, operating cost, alteration/replacement cost, and other associated costs are confirmed, and the time of occurrence of each cost is verified. Because these cost items occur at different points in time, it is important to convert each cost to the value at a single point in time. (iii) The LCC is calculated for each alternative by adding up the costs according to the type for each alternative. (iv) The related indices are calculated to evaluate the economic feasibility (the LCCA) including the net savings, savings-to-investment ratio, and payback period. In addition, a sensitivity analysis can be implemented to complement the LCCA methodology, which will provide reliability to the LCCA results.

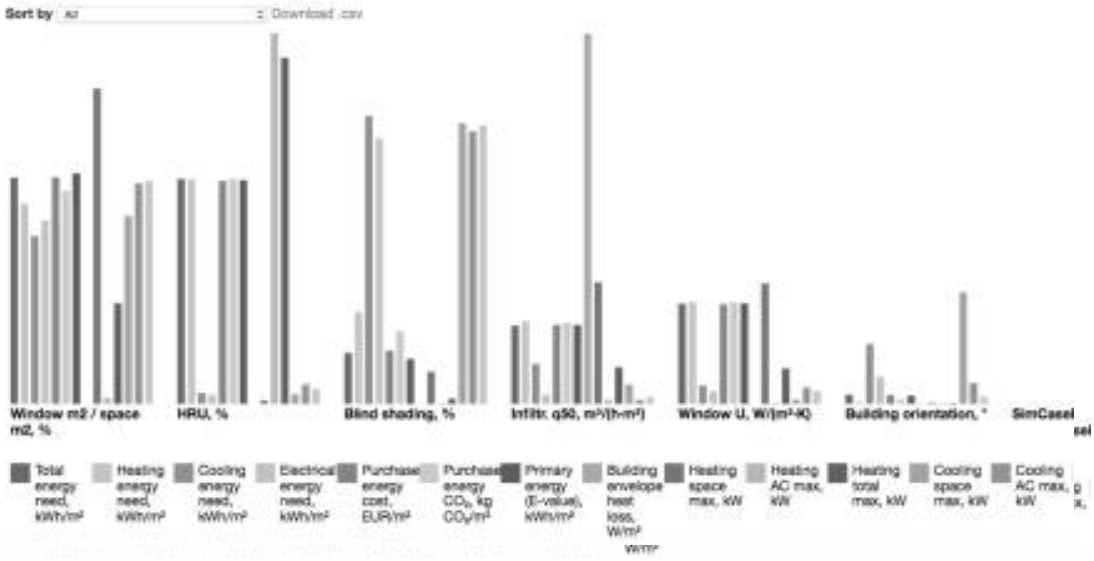

Figure 1: Visualization of the of key variables through a sensitivity analysis

5.3 Sensitivity Analysis

The subject of sensitive analysis (SA) is to learn about the influence each design variable has on the studied KPIs. This knowledge is needed to perform educated design changes to improve the design in exactly the desired way. The aim of the sensitivity analysis step is to find a design with optimised KPIs. Figure 1 illustrates a sensitivity analysis example.

5.4 KPI Visualization

Applying analytics to conceptual design has proven difficult because a problem typically has multiple targets and is imprecise with respect to one or more of these objectives (Shaw, Miles et al. 2008). The interaction of professional expertise and computer-based exploration therefore is essential for the process to be successful. Facility managers need to be able to understand general performance trends as well as variable sensitivities in order to make informed decisions in guiding the optimization process. Advanced plotting tools that enable multi-dimensional data visualization have proven useful for this purpose. such as pareto graphics (Khajehpour and Grierson 2003), hyper radial visualization, parallel coordinate (Parmee 2005; Parmee, Abraham et al. 2008) plots and radar charts have proven useful for this purpose.

Parallel Coordinate Plot (PCP) is a simple way to visualize multi-dimensional data in two dimensions as shown in Figure 2. PCP shows each of the desired variable and the KPIs are presented in parallel to the coordinate axes. Each axis can have its own value range and can either be continuous or discrete variables. Discrete variable axis enables the use of non-numerical values. The visualization shows the result obtained or the results of the values of the variables depending on the approach taken, and combined these with a certain result of all the values of the line between the axes.

Although the number of variables and the objective function that can be presented in this type of visualization can be infinite, the large amount of variables will make the visualization difficult to read and find correlations of the variables may be difficult. Appropriate use of the quantitative objective function variables and visualization strategies facilitate the use and understanding.

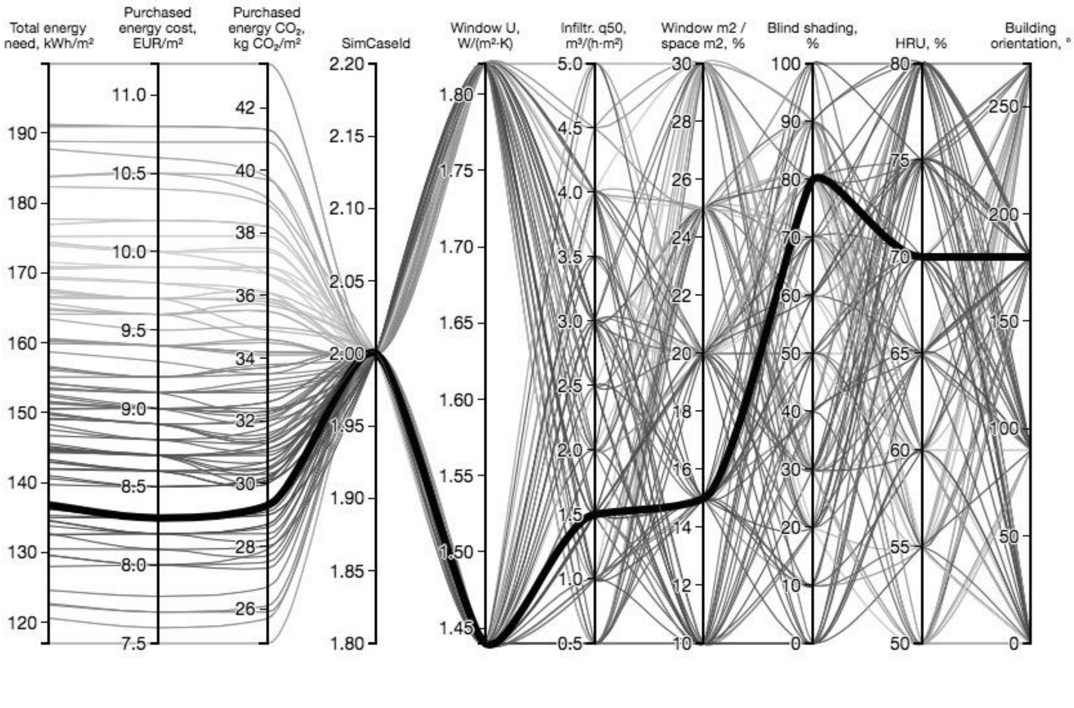

Figure 2: Parallel coordinate plot for the decision-making using the developed multi- KPI analysis prototype tool.

The value of the variable ranges can be adjusted so it facilitates the selection of the best solutions within a desired number of parameters and therefore achieve the best desired result. It is also easy to visualize by assigning to each result and its constituent variables on the line that falls within the desired ranges. The color visualization also helps to determine the most appropriate solution. By utilizing interactive visualization options to restrict the values of the parameters and their results, so that solutions that not fall within those parameters will change colors to for example, gray, therefore we can better focus on a limited number of solutions.

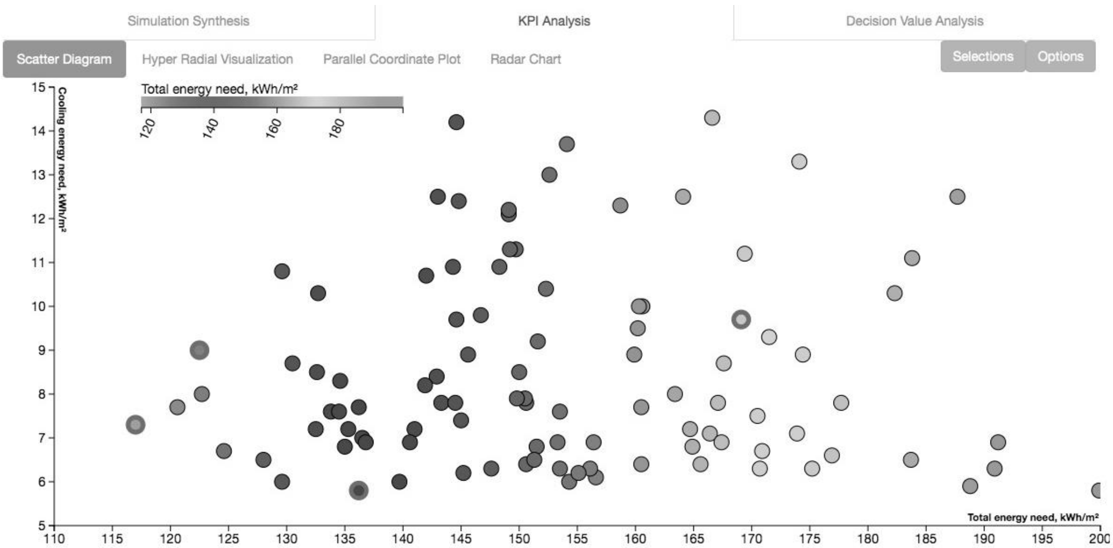

Figure 3: Decision making analysis via scatter diagram.

The scatter diagram is usually used to analyze the relationship between two variables. The pattern of the intersecting points can graphically show the relationship of the variables and usually validate or invalidate cause-and-effect relationships. Scatter diagram graph can be represented in two variables of the objective function, however a third variable is also possible but projection a three-dimensional visualization could be difficult to read and interpret in practice. A more intuitive way to use the third dimension is the coloring of the points of the third objective function value and the color legend, graphs, presentation as shown in figure 3.

6. Conclusions

As described above, FM is a complex and fast growing business that responds to the demands and economic pressures of the built environment. Latest trends indicate that FM, which traditionally focuses on technical issues, is having stronger impact on a strategic level. In other words it is developing from purely technical to more market driven service. The role of facility managers in early design should become more prominent. The use of different BIM tools enables FM professionals to make various long term predictions. The Multi-KPI which gathers different simulation results could be a powerful tool to be used by facility mangers to visualize different KPIs related to FM that can improve can their decision making process.

Identifying the Inefficiency and Poor Performance of the Delivery of Services

Alfredo Rivera[1], Dean Kashiwagi[1] and Sicco Santema[2]

[1]School of Sustainable Engineering and the Built Environment, Arizona State University
[2]Delft University of Technology, Netherlands
Email: AlfredoORivera@asu.edu

Abstract

The construction industry has had a history of non-performance in the delivery of services [in terms of on time and on budget]. Other industries such as IT and professional services have also experienced non-performance. The problem seems complex, as there are many participants who are involved in the project non-performance including the owner, the buyer, the vendor, sub vendors, manufacturers, designers, and project managers. An industry structure analysis proposes that the problem is caused by parties managing, directing, and controlling (MDC) another party. This could happen anywhere in the supply chain. This paper proposes that a major source of the non-performance in projects is caused by project managers who are managing the projects from the different construction supply chain participants including the owner, the designer, the vendors, and procurement. This has been identified in numerous project tests where the objectives of the test was to minimize the MDC in the projects and the major difficulty was the resistance from project managers. The paper also proposes that the project managers are educated to manage, direct, and control in their education and training, including their professional certifications from the Project Management Institute (PMI) and the International Project Management Association (IPMA).

Key words: project management, risk management, low performance, resistance to change, delivery of service

1. Introduction

Organizations in the construction industry have had problems with delivering services on time, on budget, with high customer satisfaction. This problem has been seen in multiple industries, particularly highly technical ones, such as construction and information technology. The poor delivery of services has been documented in the construction industry worldwide for over 30 years (Latham, 1994; Egan, 1998). However, after many years and billions of dollars invested in research, the solution remains elusive (Goff, 2014). Similar to the construction industry, the information technology (IT) industry has had similar documented performance information of poor delivery of services, and has struggled to efficiently and effectively complete projects since its origins. A literature search has identified the source of the problem is still unknown to industry in consistently and efficiently delivering high performance services. Very few in industry and academia have created a successful hypothesis, run cycles of tests, which resulted in the changing of industry practices (Kashiwagi, et al., 2008). The most impactful research identified, has led to conclusions that pre-planning is critical, hiring contractors who have expertise will result in better performance, and risk is mitigated when the supply chain partners work together, and expertise is utilized at the beginning of projects. One of the issues making it difficult to identify the problem of the poor delivery of services is the number of parties involved in the supply chain. The supply chain parties are segmented into various silos of communication. Each silo communicates using technical jargon. The technical communication increases complexity and make it more difficult to identify the source of inefficiencies. Research has also shown that the continued education of industry participants maintain the status quo and are perceived to be ineffective in driving positive change (Goff, 2014).

2. Problem

Due to the current reactive environment of delivering services, the result has been ineffective (Lepatner, 2007; PWC, 2009; Yun, 2013). Research has shown the following poor performance metrics:

- 2.5% of projects defined as successful (in terms of completing the full scope, on time and on budget).
- 30% of projects are completed within 10% of original planned cost & schedule.
- 25 to 50% of projects do not efficiently align labor on projects.
- Management inefficiency costs owners between $15.6 and $36 billion per year in the world.
- Rework by contractors is estimated to add 2-20% of expenses to a contractor's bottom line.
- An estimated $4 billion to $12 billion per year is spent to resolve disputes and claims.

The industry has struggled with overcoming poor delivery of services, and has not seen any significant improvement in the last 3-6 decades. The fact remains that the industry as a whole does not understand the source of its own problem and has not done anything effective enough to fix it. The problem is also being proliferated by multiple parties: manufacturers of systems and materials, owners, buyers, owner project managers, procurement personnel, general contractors (GC), subcontractors (SC), and GC/SC project managers. Literature research has shown that both the construction and information technology industries having significant documentation of the performance of the delivery of services. Both industries have had similar results. In the United States, construction performance has been low (Kashiwagi, 2013):

- Productivity has decreased by .8% annually.
- Construction companies have the second highest failure and bankruptcy rate (95%).
- Over 90% of transportation construction jobs are over budget.
- Almost 50% of time is wasted on job site.

According to numerous reports in information technology, the poor delivery of services has been similarly documented (Kashiwagi and Kashiwagi, 2014):

- US Accountability office identified 413 IT projects--totaling at least $25.2 billion in expenditures for the fiscal year of 2008 as being poorly planned, poorly performing, or both. With just under half being re-baselined at least once.

- European Services Strategy Unity reported 105 outsourced public sector ICT projects with 57% of contracts, which experienced cost overruns with an average cost overrun of 30.5% and 30% of contracts which were terminated.
- McKinsey & Company analyzed over 5,400 projects and reported 50% of IT projects on average are 45% over budget, 7% over time, 56% less value than predicted, and 17% of projects end so badly they can threaten the life of the company.

In a recent study to better understand why the performance of the delivery of services was poor, it was identified that the current delivery systems and management theories have been based on management, direction, and control. The study reviewed 780 publications in five major databases [EI Compendex, Emerald Journals, ABI/Inform, Google Scholar, and ASCE Library]. From the 780 publications reviewed, 103 delivery systems were analyzed and compared. Additionally, 10 company management models were assessed. Lastly, the top 22 major buyer/supplier theories were identified including: Lean Construction, Supply Chain Management, Total Quality Management (TQM), Just in Time (JIT), Project Management Body of Knowledge (PMBOK), and Conflict Management (Kashiwagi, 2013). In the study, the authors identified some management experts (e.g. Marcus Buckingham, Jim Collins, Edward Deming, Peter Drucker, W.L. Gore, and Ricardo Semler) that proposed that the management, direction, and control methodology is not an effective or efficient approach. Though repeatedly implemented by the management experts over the past seven decades, the non-traditional idea has not been recognized as a valid solution by current delivery methods or management theories. According to the management experts identified, MDC may be the cause of project nonperformance. Additionally, they identified the following as more accurate alternative concepts of practice to improve performance:

- Adjust structure to fit the constraints of the people.
- Select the right people and put into right position.
- Formulate team philosophy, draft people to fit into the philosophy, then change the philosophy to match the constraints of the people you drafted.
- Use the strengths of people.
- Take the path of least resistance; let nature take its course.
- Shift management model to an alignment model, which sets the environment and the course of the organization.
- Remove management, and create transparency, resulting in increased accountability of all stakeholders.
- Set up alignment model that empowers employees to choose their own work and who they will become accountable to until completion of work.

3. Proposal

The researchers propose to look into the traditional idea of management, direction, and control (MDC) to identify if the concept increases performance. The researchers propose to identify the results. If the results identify MDC does not improve performance then to create a new project management model that is not based on MDC and see if it can help resolve issues occurring in the industry.

4. Methodology

The researchers propose a mixed methods approach to carrying out the proposal, involving two types of research: Literature and Case Study research. To identify if MDC improves performance the following will be performed:

1. Identify the success of MDC in solving major social issues
2. Identify if construction has experienced the same results.
3. Confirm the potential source through testing.
4. Identify key components in the industry who can test out the solution.
5. Identify how to document, and proliferate the solution in the key components.

5. Success of MDC in Solving Social Issues

A literature search was performed to identify if the idea of management, direction, and control is a viable option to improve performance. In order to better understand this idea, and if it parallels what the management experts have identified, the researchers looked outside of the delivery of services area. The researchers identified dominant examples in society, where the principles of control were implemented. The goal was to potentially gain additional insights for the entire professional services community, to either strengthen the argument for or against the use of control principles. Some of the most dominant examples of societal issues were identified such as Prohibition, Drug War, Gun War, Prison System, and Immigration.

5.1 Prohibition

Prohibition will forever be one of the most dominant examples of one entity failing to control another. The United States just finished World War I and due to the progressive era [widespread social activism and political reform] in the U.S. in the late 1800's and early 1900's, alcohol consumption and politics were perceived to go hand in hand causing government corruption. In fact, many factions, including religious organizations were at the heart of the discussion. It was not until January 1917 that Congress first convened and began discussion and partial implementation of the removal of alcohol distribution to restrict access. On October 28, 1919, Congress officially passed the Volstead Act, overruling President Woodrow Wilson's veto, to enforce the eighteenth amendment (prohibition). Prohibition went into full effect January 1920; until it was repealed, December 1933 by the ratification of the twenty-first amendment signed into law as the Cullen-Harrison Act by President Franklin Roosevelt. The devastation that the era of prohibition left in U.S. history has been extraordinary. In total, the prohibition lasted nearly 14 years, and started with great intentions to decrease crime through the removal of alcohol distribution and access to consumption (Burns, et al., 2011; Tracy and Acker, 2004). What actually occurred was the following:

- Increased law enforcement.
- Increased funding.
- Increased access to alcohol.
- Increased alcohol consumption.
- Increased criminal activity.
- Decreased taxes collected through alcohol.

The government's attempt to control the American people attempting to restrict access and consumption did not work and only increased costs without decreasing access or consumption. People will always do what they want. Some additional dominant statistics are the following (Blocker, 2006; Peck, 2011; United States, 2008; US Treasury Department Bureau of Industrial Alcohol, 1932; Warburton, 1932):

- Prohibition law violations increased 102%.
- Drunkenness and disorderly conduct increased 41%.
- Drunk driving increased 81%.
- Theft and burglary increased 9%.
- Federal convicts increased 561%.
- Total federal expenditures increased 1000%.

5.2 Drug War

Popularized by President Richard Nixon in 1971 with his public declaration "America's public enemy number one in the United States is drug abuse," the drug war has its roots starting in the 1800s. Opium was beginning its popularity in the American Civil War, and cocaine was just as popular. Drugs like cocaine, heroin, and morphine were readily accessible for medicinal purposes in both health drinks and remedies. Due to an increase in addiction to these drugs, the first set of regulations to control it and restrict access was in 1906 when the Pure Food and Drug Act began requiring doctors to label their medicines. Shortly after, a number of increasingly more serious regulatory statutes took effect, such as the Harrison Narcotics ACT in 1914 (first federal drug policy), down to the creation of the Federal Bureau of Narcotics in 1930 (Sharp, 1994; Rosenberger, 1996). Though many attempts to restrict access and consumption through regulation was good intentioned, it found its match during the flower revolution of the 1960's. Access to drugs and its consumption was at an all-time high during this decade, to the point that it caused the newly elected President Nixon to make an address against drugs that has lasted over 40 years. Not using hindsight and learning from Prohibition regarding restriction of access and consumption of substances, the war on drugs has utilized more resources and seen less improvement than the Prohibition of 1920.

Interestingly, the U.S.'s second attempt to use MDC to restrict access and consumption of substances has resulted in the following (Drug War Facts, 2014):

- Increased funding from less than $100M to over $25B.
- Increased law enforcement.
- Increased arrests from 1M to as high as 2.5M.
- Increased prison population over other arrests by over 50%.
- Maintained or increased drug use.

5.2.1 Portugal/Netherlands/Canada/Uruguay

Realizing the drug war has increased cost without decreasing consumption or criminal activity, four countries (Portugal, Netherlands, Canada and Uruguay) have all decided to decriminalize the use of drugs in some way. The Netherlands decriminalized drugs in the 1970's, Portugal in 2001, Canada in 2003, and

Uruguay in 2013. The Netherlands and Portugal governments created committees of the smartest minds to study the effects of drugs and the cost to continue enforcing rules and regulations. What is interesting though is in the Netherlands, all drugs are illegal, but the government recognizes any form to control it only causes greater issues. Instead, they have tolerated the use of drugs at a certain limit sold in coffee shops, which has resulted in drug use levels no greater than other countries and drug related deaths (2.4M) being the lowest in Europe (Mayer, 2014; Hari, 2015). According to the latest performance information published on Portugal's decriminalization of all drug use, the numbers show similar results (Aleem, 2015):

- Continued drug use decreased from nearly 45% to less than 30%.
- Drug induced deaths decreased from nearly 80% to less than 20%.
- HIV infections decreased from nearly 45% to less than 10%.
- Increase in drug treatment by nearly 50%.

What each of these countries realized, was the prevention of drug use by increasing control does not work, and it is better to help align the people then punish them.

5.3 Additional Dominant Control Examples

There are many other examples documenting the inefficiency of control, and how the use of no control, has increased production and reduced cost and time:

1. Gun Laws – the U.S. "removal of guns" activists have attempted to have laws passed as a form of control to decrease access to guns and deaths of violent gun users. This attempt to prevent the access to guns and prevent death has only increased cost of the ATF (Bureau of Alcohol, Tobacco, Firearms and Explosives), without a significant decrease in deaths or access (U.S. Department of Justice, 2010).
2. Prison Systems – The U.S. thought that it could control the people they incarcerated to educate and rehabilitate them to prevent them from committing further crimes. The U.S. in general has been unable to reduce the number of law breaking individuals through incarceration, and has been one of the largest failures of control (ProCon, 2010).
3. War on Poverty – In the 1960's the U.S. declared "war on poverty." It has tried to use control to level the poverty in the U.S. through multiple government-controlled programs. The reduction of poverty has not been successful (National Poverty, 2014).

History has identified that one entity cannot control another entity; therefore, any attempt to manage, direct, and control someone should produce consistent predictable results of low performance. Similar to the findings of the management experts that any attempt to use management, direction, and control are not effective and efficient, has become evident in the social case studies presented. The pattern identified seems to be that when one entity attempts to manage, direct, and control others, the opposite desired outcome occurs instead. Whenever control is exercised, the following occurs:

- Cost increases.
- Time and resources increase.
- Increase in stress and decision-making.
- Risk increases.
- Overall performance diminishes.

Based on observation and deductive logic, the practice of MDC is inaccurate and increases risk. In the whole history of man, many people have attempted to control others with no success. The delivery of services is no different. The industry has been plagued with MDC, and it is the leading cause for all poor project performance (Kashiwagi, 2013).

6. Longitudinal Case Studies: Minnesota and MEDCOM

In order to better understand if MDC was a viable option to improve performance in industry, a two six-year longitudinal study [users in the state of Minnesota and the U.S. Army Medical Command (Table 4 and 5)] was conducted. Each user used a best value (BV) system called the Performance Information Procurement System (PIPS). PIPS is a revolutionary approach to improving the delivery of services. PIPS proposes the replacement of management, direction, and control with the utilization of expertise. The system was first conceived in 1991 as part of Dean Kashiwagi's dissertation (1991). PIPS was originally, strictly a selection process. The first test of the process was performed in 1994, used to select roofing systems and contractors for private organizations including Intel, IBM, and McDonald Douglas. The system was documented and performed so well for the roofing industry, the system spread to other construction areas. PIPS has since been tested in the entire supply chain (construction and non-construction services). Its developments have been researched and developed, by the Performance Based Studies Research Group (PBSRG) out of Arizona State University (ASU), in support of professional groups like the International Council for Research and Innovations in Building and Construction (CIB) and the International Facility Management Association (IFMA) for the last 23 years, and has been identified as a more efficient approach to the delivery of professional services. It has identified that the main cause of non-performance in delivering services is due to management, direction, and control. The two studies identified the following similar issues:

- Inefficient internal management structure.
- Poor performance in the delivery of services.
- Did not know how to identify the performance of their services.
- Looking for an approach to help them improve their project performance.
- Needed a way to improve the management structure.

The BV system identified the following observations:

1. BV application has been a total success by providing transparency.
2. Expertise lowers costs and increases performance.
3. An expert vendor can accurately identify a projects scope and cost.
4. Measurement brings transparency and minimizes decision-making and MDC.
5. A visionary core team must be organized that is optimal in terms of a high-ranking visionary leader, and visionary project management and procurement components.

Table 4: U.S. Army Medical Command Best Value Performance

Overall Schedule Delay Rate	*47.17%*	-	*35.31%*	*1.59%*	*16.38%*	*7.44%*	*51.68%*	*12.73%*
Owner/Client	*21.92%*	-	*15.26%*	*0.00%*	*7.41%*	*3.93%*	*24.13%*	*5.45%*
Designer	*4.47%*	-	*5.69%*	*1.59%*	*8.97%*	*0.00%*	*4.48%*	*7.27%*
Contractor	*2.65%*	-	*10.93%*	*0.00%*	*0.00%*	*3.51%*	*2.42%*	*0.00%*
Unforeseen	*4.54%*	-	*3.42%*	*0.00%*	*0.00%*	*0.00%*	*5.04%*	*0.00%*
Number of Satisfaction Surveys	*233*	*0*	*2*	*18*	*0*	*0*	*212*	*1*
Vendor	*9.5*	-	*9.0*	*9.9*	-	-	*9.5*	*8.8*
Selection Process	*9.7*	-	*8.5*	*10.0*	-	-	*9.6*	*10.0*

Table 4 and 5 both identify the results of both studies. The following conclusions were made:

- The owner/client and their representatives were the biggest source of project deviations.
- The BV PIPS minimized the cost and time deviations.
- The vendor performance was outstanding when the owner/client minimized MDC.
- Cost was minimized and within the budgets.

7. Analysis

The research conducted by PBSRG identified the solution to the inefficiency of delivering services was in the overall structure of the industries and not a technical issue in any of the industries. It also showed the potential of the BV PIPS [utilizing expertise] to improving industry performance. Each BV case study shows a dominant improvement in performance of delivering services, simultaneously decreasing owner/client MDC. The case studies support the following concepts of the BV approach:

- The replacement of MDC with the utilization of expertise may be the most needed change required to improve industry performance.
- The utilization of expertise leads to lower costs, higher performance, and value. This is despite some industry perception that expertise is too costly. Then, when faced with massive failure due to the utilization of vendors without adequate expertise, they blame the complexity of the projects.
- If the expert must be managed, directed, and controlled, they are defined as a non-expert.
- Transparency minimizes the level of complexity and increases the value of experts and their expertise.

8. Proliferating the BV Solution

The very successful BV approach has been researched and developed for 22 years in construction and non-construction industries, and has been shown as an alternative to delivering services with documented performance information. It has been identified as a complete procurement/risk management system. The same technology has been taken into the classroom of the ASU Barrett's Honors program, and has had the following results:

1. Most popular Honors class at ASU [Rate my professor rating of 4.9 (out of 5.0), 150 slots fill up in less than an hour, ASU engineering class ratings of 4.7 (out of 5.0), led to identification of Dr. Kashiwagi being one of the top teachers in 2013].
2. Students with problems have made drastic improvement in their personal lives to stop taking pharmaceuticals, stop drinking, implementing a life makeover, becoming transparent, and having an increase in accountability and responsibility.
3. Students learn complex concepts four to five times as quickly using natural laws, simplicity and common sense.

The Barrett's Honors College has exposed the innovative solution to 7th and 8th graders in summer programs. The results have been outstanding. The high school education effort has paved the way for additional BV endeavors. The curriculum from the course has been compiled into a single class package that can be incorporated into any educational program. The results of the BV college and high school courses has led to additional key partnerships:

- St. Louis High School, a prominent school in Honolulu, Hawaii, has adopted a semester-long curriculum in the fall of 2015. A second private school in Honolulu is also interested in the education program
- A successful summer 2015 program was tested on 116 undergraduate Brazilian engineering students. This effort was carried out to identify if the BV-FM education could be taught quickly (in two months) and could attract students with limited English capability to the methodology.
- Tempe High School has initiate a semester long leadership academy at the first high school in the Tempe School District. The program is being pushed by an ASU coordinator who has watched the ASU honors program, the Barrett Summer Scholars program, and the 2015 successful Brazil undergraduate engineering program

Many other entities in the supply chain can benefit from the testing and implementation of the BV solution to include PMI, IFMA, IPMA, NIGP, Union organizations, Owners, Contractors, Manufactures, K-12 institutions, and Universities. The future of delivering services is to educate professionals to become someone who can utilize expertise and not manage, direct, and control. They must be able to escape their silo to increase value to the company by utilizing expertise to minimize cost.

9. Conclusion

Organizations have struggled for decades to deliver services efficiently and effectively. Due to increasing numbers of parties in a supply chain, projects have become more complex and less transparent. Due to the complexity of projects, management, direction, and control has become a staple practice in attempt to increase performance. Many project management models and delivery systems have not moved from the practice of management, direction, and control, and it has been identified as the leading cause for non-performance. Management experts such as Deming, Buckingham and others, along with dominant societal case studies such as the Prohibition and the Drug War have clearly identified that any attempt to manage, direct, and control others will result in low performance. A new approach called BV PIPS, which shifts the use of management, direction, and control to utilizing expertise, has been significantly documented to improve the performance of delivering services, and closely relates to the principles of no control identified by such management experts. The researchers further identified that the same solution, BV PIPS, is applicable to all supply chain participants in all industries, and the most important participant is the “project manager” who is doing the integration between silos in the supply chain. Lastly, the BV approach education program has been shown to successfully increase the number of highly qualified entrants into the professional industry. In testing the education curriculum on college and high school students, it has been found that students of varying ages, backgrounds, and degrees of study can learn proven high-performing industry management techniques. Students can begin learning these concepts at a young age, thus creating a pipeline of competent students entering industry. The researchers recommend future research to take project managers and propose a methodology to educate, apply, and document the results of their efforts, as well as create a pipeline of qualified and competent young students entering industry.

Lean Collaboration Services One Click Away – Should We Stay or Should We Go?

Eelis Rytkönen, Vitalija Petrulaitiene, Tuuli Jylhä and Tatu Pakarinen

Aalto University, Finland
Email: eelis.rytkonen@aalto.fi

Abstract

Ability of individuals to work independent of time and place alter the optimal way of supporting core tasks of mobile workers in physical and virtual environments. Information resources are increasingly accessible to individuals, decision making power is shifting from organizations to individuals, sizes of organizations shrink, number of organizations increases and value is increasingly generated by smaller collaborating actors in networks rather than massive individual organizations. These shifts make collaboration facilitation more complex: partnering organizations and their employees are more and more scattered which creates demand for services that connect people to collaborate physically and virtually.

Collaborative practices, such as meetings and workshops, are being arranged and managed in both physical and virtual environments. Collaboration that takes place in virtual platforms is usually considered less time-taking and more sustainable in terms of carbon footprint but often include major technical nuisances. On the other hand, face-to-face collaboration can be considered more straight forward and fruitful but getting everyone in the same meeting room at the same time can be a challenge.

Therefore, this paper explores the service potential of facilitating collaborative practices by supportive services that are manifested in virtual and physical dimensions of space. It aims to increase understanding on the literature gap between virtual and physical work environments and reflect it to literature on collaborative knowledge work. It does so by first introducing lean management approach and knowledge worker typologies. Second, it discusses results of fourteen interviews and three workshops on collaborative knowledge work practices. Third, it synthesizes the results. Fourth, it discusses the implications and limitations of the study.

Keywords: Collaborative practice facilitation, Facilities management, ICT management

1. Introduction

Knowledge workers can increasingly work independent of location and time (Laing 2014). Technology enables flexible working opportunities providing more freedom of choice regarding where, when, with whom and how each individual works. At the same time, the ability to dictate work habits from the top of the organisation down to individual employee decreases. Organizations are becoming flatter, boundaries between organizational silos are blurring, and increased flexibility allows more agility and change responsiveness (GSA 2009). The new setting requires more proactivity from both the organizations and the employees.

At the same time, According to a study with 578 respondents on national meeting habits in Finland (Kokousbarometri 2015), an average employee attends seven meetings in a week, spends nine and a half hours attending meetings and over six hours to other meeting-related tasks weekly. With the average of six persons attending each meeting, one meeting is worth an individual work day, eighteen per cent of the meetings are arranged from a distance, a fourth of the meetings were considered to be possible to arrange without a meeting and 42% of the meetings are considered inefficient. Three fourths of all the meetings were reported to be internal. 56 % of the informants of the study thought that there are always or seldom too many meetings.

But the dilemma is that an increasing amount of value and knowledge is co-created 1) through internal collaboration interactions in groups rather than by any single employee alone, and 2) through external collaboration together with the partners and the customers. The increased freedom causes a variety of manners of conducting tasks which does not come without its implications. It is increasingly difficult to match times, locations and activities with peers, colleagues, clients and partners. Need for collaboration exists but an increasing amount of time is wasted in trying to collaborate rather than collaborating both in physical and virtual spheres. Collaboration activities require thus more effective facilitation and services to support them.

To understand the collaboration dynamics in physical and virtual spheres, this paper outlines the opportunities and challenges in arranging collaboration activities face-to-face and from a distance. It aims to increase understanding on service potential regarding support for collaborative knowledge work.

It does so by first introducing lean management approach and knowledge worker typologies. Second, it makes an overview of novel collaboration tools available on the market. Third, it discusses results of fourteen interviews and three workshops on collaborative knowledge work practices. Fourth, it synthesizes the results. Fourth, it discusses the implications and limitations of the study.

1.1 Literature overview

1.1.1 Lean approach to physical and virtual collaboration

Lean thinking is a business management approach which aims to capture customer value in value creation phase (Koskela 2000). Lean can be approached through three main concepts:

customer value, waste and continuous improvement (Jylhä 2013). Increasingly, as the value is co-created with the customers (Grönroos and Ravald 2011), customer value refers to the subjective perception of a service or a product for the customer. Waste refers to the types of activities that are conducted but that do not create any value for the customer (Jylhä 2013). Continuous improvement refers to the requirement of constantly improving processes and operations to minimize waste and to stay competitive in customer value creation (Jylhä 2013).

Two valid measurement concepts in lean especially in regards to collaborative activities are resource efficiency and flow efficiency. Resource efficiency is about optimizing at the level of an expert individual. Flow efficiency is about optimizing as a team for a feature. (Rothman 2015). In terms of lean for collaboration, the latter is more valid.

Lean concept originates from Japanese car industry and has been largely used in product development practice (Rothman 2015). It has also been introduced in the field of construction management (Koskela 2000) and more recently in real estate management (Jylhä 2013). In addition, scholars in IT production have discussed lean (Plenert 2012). Lean has also been discussed in the context of team effectiveness between teams that regularly meet face-to-face (Van Dun and Wilderon 2012) and those that are globally virtual (Maznevski and Chubova 2000).

Van Dun and Wilderon (2012) outline five fundamental rules in literature of Lean orientation to management:

1. Specify the value-creating and non-value creating activities from customer perspective.
2. Identify all the necessary steps to produce the service across the whole value stream.
3. Ensure that value-creating actions flow without interruption.
4. Only make what the customer requests.
5. Continually remove waste at work as it is uncovered.

They furthermore identify four main enablers for effective lean team collaboration: Higher level leadership Support, Strategic and Structural clarity, HR policy, Resource Abundance.

However, there are no studies looking at lean as an overarching approach to compare physical, virtual and hybrid ways of collaborating in teams. Therefore, this piece of research aims to build bridges over the disciplinary silos by focusing on identifying the customer and the waste types in collaboration activities in knowledge work.

1.1.2 Knowledge worker as a customer in physical, social and virtual spheres

So if the organisations consist of individuals and the aim of workplace infrastructure is to support organisations, let us assume that a lean team is an ideal way of removing waste from organizational knowledge practices. The question for the managers of the supporting infrastructure then is: What does it take to facilitate these knowledge workers in the future?

To identify what actually creates value for the customer, we need to first identify the customer. In the context of providing services for collaborating knowledge workers, the demands are heterogeneous. The dilemma is that not all the knowledge workers are the same, not all their activities are the same, and not all their demands are the same. The most suitable working styles for each individual depend on the relative tasks, abilities, personal preferences and relationships with other members in relation to the organization, the team and the projects underway. Then again, not all the individual wishes can be fulfilled as individuals tend to be selfish and might not see a greater good. An interesting example is that of Yahoo's back to office campaign some years ago.

There are various approaches to categorizing knowledge workers. We hereby briefly review some of the most recent shifts and typologies from social, virtual and physical knowledge facilitation aspects. The most relevant points are listed in Table 1.

Table 1. Literature insights on knowledge worker types and supportive services from different branches

	Approach	Conclusion	Field of research
Van Dun and Wilderon (2012)	Enablers for effective lean team collaboration	Higher level leadership Support, Strategic and Structural clarity, HR policy, Resource Abundance	Lean for knowledge management
Reinhardt et al. (2011)	Knowledge worker roles and actions	Personas of controller, helper, learner, linker, networker, organizer, retriever, sharer, solver and tracker.	Knowledge management
Morgan (2015)	Shift from knowledge workers to learning workers	Learning overcomes knowing.	Knowledge management
Bennett et al. (2012)	Four generations at workplaces	Facilitation of knowledge exchange between generations through mentoring millennials, teamwork, collaborative working and virtual workplace.	Physical workplace management
Lake (2014)	Smart flexibility	Flexibility means the same work with different tools at different times in various locations.	Physical workplace management
Matthews et al. (2011)	Collaboration personas	Collaboration personas for Community of practice, Project team and Task team.	Virtual workplace management
Miller and Marsh (2014)	Digital renaissance	Technology is most effective when invisible.	Virtual workplace management

From the social knowledge facilitation point of view, Reinhardt et al. (2011) outlined nine roles and action types of knowledge workers that all contribute to the overall organisation: Controller, helper, learner, linker, networker, organizer, retriever, sharer, solver and tracker. Morgan (2015) suggests that the whole concept of a knowledge worker is challenged by that of learning workers as knowing is not useful anymore when all the knowledge is available but rather ability to learn.

On the other hand, from the physical knowledge facilitation side, Bennett et al. (2012) discuss the tricky situation of facilitating four different generations at workplaces at the same time and approaches the problem from a merely demographic aspect. In general, the technical capabilities and attitudes towards working between the generations are different and in addition, the heterogeneity among each generation is huge. Bennet et al. (2012) suggest four workstyle criteria to overcome these problems: Mentoring Millenials, Teamwork, Collaborative working and the Virtual workplace.

Lake (2013) introduces the idea of flexible working. In his view, flexible working is not about doing a radically different kind of work. It is about doing basically the same work with different tools at different times in various locations. Both of these dynamic ideas increase individuals' autonomity, proactivity and demand for education and common rules for collaboration.

Matthews and her peers (2011) propose collaboration personas as a design tool for workplace collaboration in the virtual sphere to unleash collective intelligence. They outline two main problems in virtual collaboration tools: the adoption problem and the use of inappropriate tools for collaboration. They argue that the end user segments in digital tool planning tend to focus on individual rather than collaboration needs. Thus, they outlined three types of teams: A *community of practice,* A *project team, a task team.* They also identified four phases of collaboration: Starting, Planning, Executing and Reporting. Miller and Marsh (2014) discuss the role of digital renaissance in the workplace, arguing that technology is most effective when it is invisible.

A proposal for the interrelations of the different dimensions are shown in Figure 1.

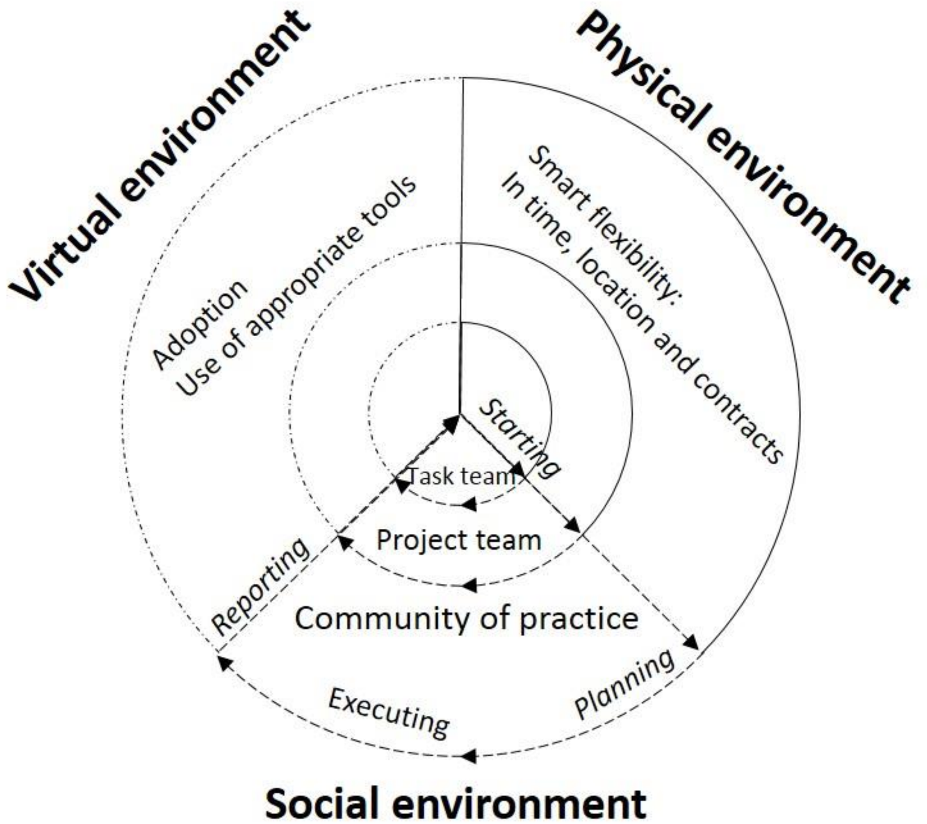

Figure 1. Interrelations of social, virtual and physical workplace environments.

Figure 1 pinpoints the demands of meeting more face-to-face in the beginning of any project and then again the ability of collaborating virtually in order to execute and report the collaborative tasks.

1.1.3 Waste from collaborating knowledge worker point of view

The actual value of any supporting service for a collaborating team of knowledge workers is getting their job done, i.e. creating value to a customer or various customers. In reality, much time is wasted in non-value creating tasks that could be automatized or totally neglected such as searching for an appropriate meeting place, ordering appropriate food, searching for a parking place, searching for emails, colleagues arriving late to meetings, connections not functioning, and so on.

So in terms of the outlined research problem, the customer is a team of collaborative mobile knowledge workers. The most simple collaboration activity, such as a meeting, can include multiple potential added values and waste flows from the knowledge worker point of view. This section explores literature on types of collaboration wastes in three scales of real estate service, office and meeting.

Jylhä (2013) identified six sources of waste in real estate services: price minimisation over cost minimisation, poorly managed information, inability to improve, unmatch between process and customer value, sub process optimization over value creation process optimization, and constantly overemployed employees.

Taylor (2014) claims that as much as 90 % of all the work in the office can be considered waste. Taylor suggests that waste in an office can be seen to include at least process, physical environment, information and people waste. In the physical sphere, the largest nuisance in an office is interruption which can happen as frequently as every three minutes (Taylor 2014). Furthermore, Taylor (2014) claims, that it takes 20 minutes to get focused again on the task one was conducting before interruption.

According to a national query in Finland, on average two hours per person per week is waste in meetings (Kokousbarometri 2015). The main nuisance was considered to be not sticking to agenda, the second largest issues was someone being late from the meeting, the third getting to the actual agenda, the fourth the decision making and the fifth the unfunctioning meeting tools and equipment (Kokousbarometri 2015). It was concluded that on average in an organization of a hundred employees, the potential savings that could be achieved by removing waste from meeting practices reach up to 1,5 million € annually and save 5 hours 22 minutes from an employee's average week.

On the other hand, offices facilitate informal encounters that can help in proceeding with projects without heavy meetings. In comparison to offices, working from home increases solitude and the amount of information waste which is the largest nuisance in the virtual sphere. One can easily get carried away by overflowing email boxes and endless social media and link jungles. Working from third places can potentially increase interaction outside the home organization but requires more proactivity from the knowledge workers.

1.1.4 State-of-the-art of available collaboration services

What kind of services are there on the market to remove the outlined wastes? There are plenty of applications to help multinational corporations in collaboration such as Trello, Fingertips, Slack, Dropbox, Microsoft OneNote, Outlook, Skype for Business, Adobe Connect, Sharepoint, Google Drive, Doodle, etc. To get an idea, this chapter outlines examples of these kinds of services that could help in removing the waste types identified in literature.

For unfunctional equipment, there tends to be helpdesks and centers but physical help is rarely available. However, some office space providers such as Technopolis offer a service where the virtual meetings begin and end automatically whenever wanted and support is available during the office hours.

For sticking to agenda, there are various types of tools that help in focusing on relevant topics. One example is Trello that provides a visual tool for organizing and following project execution. Another software is called Fingertip which helps before, during and after the decision making with various integrated tools. In physical sphere, there are various small and medium sized consultancies that provide professional – usually thematic - facilitation services such as Fira Verstas.

For the waste theme of unfunctional tools for information processing, there is a vast variety of softwares and applications available. The softwares tend to focus on a specific task of organizing, sharing, reporting or executing a task. The problem is, however, that they are not always integrated, meaning that the application may not discuss with each other. That is why for example a company called Apped mainly provides mobile applications that are always integrated to the business softwares.

To overcome the waste of getting to the agenda, applications such as Trello, Fingertip and Onenote help by visualizing tasks, responsibilities and following the decision making. Fingertip also provides a larger tool box for planning before, executing during and analyzing after decision making.

For motivating latecomers to be on time, there are not as many solutions on the market, but Latejar is an example of a gamelike app where people are motivated to come early because otherwise they would need to pay to the Latejar based on the time they are late.

Table 2. Examples of waste types in different scales and dimensions

Waste in real estate services (Jylhä 2013) for community of practice (Matthews et al 2011)	Waste in office (Taylor 2015) for project team (Matthews et al 2011)	Waste in meetings (Kokousbarometri 2015) for task team (Matthews et al 2011)	Mainly manifested in dimension	Existing services
Price minimisation over cost minimisation	Physical	Unfunctional equipment	Physical	ie. Technopolis help center, Sharepoint
Poorly managed information	Information	Not sticking to agenda	Virtual	ie. Trello, Fingertip, Facilitation consultancy services such as Fira Verstas.
Inability to improve		Unfunctional tools to process information		ie. Trello, Slack, Fingertips, Outlook, OneNote, Yammer, Twitter, Facebook, Whatsapp, Silverbucket, Apped, Sharepoint, Doodle, Google Drive, Dropbox, QlikID, Salesforce.
No match between process and customer value	Process	Getting to the agenda	Social	ie. Trello, Fingertip, Onenote, Facilitation consultancy services
Sub process optimization		Decision making		ie. Fingertip
Employees are constantly overemployed	People	Latecomers		ie. Latejar

This literature and market overview outlined a proposal for approaching collaboration in physical, virtual and social dimensions of space. The proposal is utilized by reflecting the empirical analyses to it in the next section.

2. Method

This paper combines literature overview and service analyses with empirical data using the approach of building propositions based on case study evidence as suggested by Eisenhardt (1989). First, it looked into the types of collaboration activities in the network era by introducing recent modern knowledge worker persona types that scholars have identified in literature in fields of knowledge, workspace and ICT management. Second, it focuses on analyzing data from 15 interviews and 3 workshops on collaborational activities in physical, social and virtual dimensions of space.

The interviews were semi-structured and they aimed to identify the typical wastes and potential sources of improvement for collaborating activities in physical, social and virtual sphere. The interviews were conducted, transcribed and analyzed by the research team consisting of four researchers from November 2014 to November 2015. The analyses were done in a two day workshop with a sensemaking technique where three of the researchers who had conducted the interviews together read and discussed each interview based on which they synthesized the results.

The analyses structured the data in three waste and improvement clusters from front-end and back-end aspects of a service organization. Accordingly, the waste types can be approached through social, physical and virtual lenses. The potential for improvement in these dimensions is introduced in Table 3.

Table 3. Potential for improvement in collaboration services in social, physical and virtual spheres

	Front-end improvement potential	Back-end improvement potential
Social	Clear package, one click away	Easily accessible services, one touch point
Physical	Location and equipment	Big data and tracking
Virtual	Education for applications	Connectivity and analyses of big data

First, it is noteworthy, that the users are individuals in a hurry who try to reach each other and be effective. Thus, simple clarity of any collaboration service is crucial in collaboration services. From the end-user perspective, it is increasingly relevant to have a clear unique package the content of which is clear, to have one touch point and be one click away from whatever is needed for the collaboration activity– so whatever one needs, there has to be one clear instance responsible for it and it has to be easily accessible. From the service provider aspect, the services must be made easily accessible and clear eventhough there would be multiple providers. The user must know one place one click and one package that is relevant for him / her.

Second, the location of collaboration activities is crucial. The informants found it irritating to be always changing places and to be searching for the optimal solution where to work in depending on whom to meet. From the service provider aspect, this means that big data usage is crucial for improving services for collaboration. So tracking collaboration activities based on which services can be directed to the right places. The same technological solutions must be available everywhere, so that users from different locations can do the same things.

Third, the management of overflowing information was considered tricky. The lack of education for new applications was seen as a major reason why technology is not in as good use as it could be and digital detox was considered a way of exiting the constant information flow. Connectivity issues were considered frustrating which must be taken care of by the collaboration service provider whether it is access to files or connecting a video conference call. Also the analyses of the real time big data has to be taken care of in order to direct services better proactively rather than reactively.

3. Results

The results propose collaboration activity guidelines that can be clustered in physical, virtual and social clusters. The improvement and waste types of these clusters can be approached from front-end (end user) and back end (service provider) aspects.

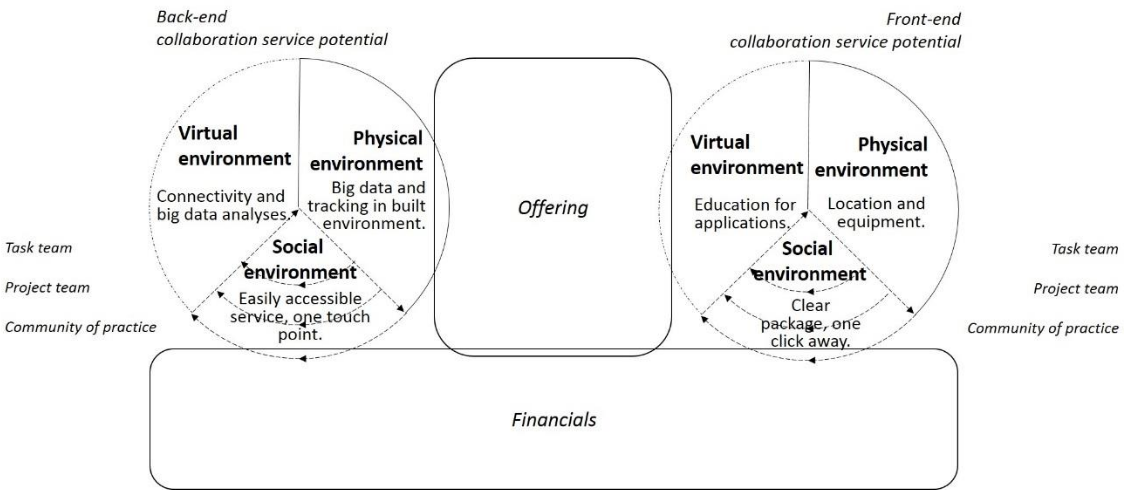

Figure 2. Proposal for collaboration service potential

It is noteworthy that different scales of teams can be supported by the collaboration infrastructure services and probably the demands are different as are the lifecycles of the scales of teams. In the beginning of any project, more collaboration that connects people physically together is required whereas execution and reporting can be more easily done without face to face meetings and usually even more effectively delivered via virtual collaboration channels. The largest service potential in the back end seems to lie in easily accessible, easy to use big data tracking, collection and analyses whereas the front-end is suggested to hold largest potential in education, relevant locations and up-to-date equipment and clear packaging with easily accessible services.

4. Discussion

There seems to be a demand for services that would support clear structures and offer collaboration as a holistic service through one touch point, one click away. Regarding the front-end, this would require effective education for the end users of the potential service in the virtual sphere, focal locations and equipment in all the locations of the physical sphere and clear packaging one click away for the end users regarding the social dimension. Regarding the back-end, this type of service would require access to multiple data sources in order to track the people and their locations and match that with the relevant collaboration space locations that would be connected without boundaries. The service should be however offered from one touch point and should be easily accessible.

The described types of services that offer some part of the components exist in the market such as Facebook, LinkedIn, Tinder, Yammer, Skype, Foursquare, Yelp, Worksnug, Venuu, Fingertip, Trello, Onenote, Silverbucket, Google Drive, Sharepoint, Dropbox and Slack among others. A competitive business idea could be to collaboratively produce and integrate the most relevant data in the back end by following big data flows in order to be able to offer a one-click away collaboration service for the end users.

5. Conclusions

This paper aimed to outline service potential of collaboration services in physical and virtual dimensions of space. It outlines a conceptual framework for developing services that would support collaboration in physical and virtual spheres. In order to develop it further, specific requirements of the collaboration personas could be explored and a prototype should be made to test its components in the market. Extensive future research is thus required in order to make the collaboration clash happen.

Abstract

Current revolutions within the consumer electronics market are having dramatic effects upon how businesses are able to deliver their services with the continued embedding of technology within our lives. Conversely, this is currently having a direct impact upon long life assets with life expectancy in the region of 15+ years, an impact, which is believed to only increase. The term asset in this context refers to systems and their internal components, for example security systems and their orthogonal components i.e. intruder detector components, CCTV cameras, recording equipment, automated security doors, controls etc. This is a rather middle to top-level view upon the term asset and components; you will find literature referring to components as the individual electrical and material elements of a product. The mismatching of lifecycles due to contrasting market conditions is driving unforeseen obsolescence investments across the Built Environment, highlighting the current neglect of obsolescence within static asset lifecycle planning. As society changes, so do the expectations of service delivery from the Built Environment. The pressures imposed by these changes upon Facilities Managers will demand resultant changes in how services are delivered, maintained and supported throughout their useful lives. It is the combination of societal demands for a greater connected, interactive and smarter Built Environment and the effects of technological change upon obsolescence that will be covered in this paper. This paper will build upon a current Engineering Doctorate project into obsolescence and asset management to speculate both the importance of developing a dynamic approach to planning asset lifecycles and possibly how this would materialise in the future. Evidence will be provided in the form of a case study, reviewed literature and current live trends, supporting the title of this paper. The main conclusions include the growing evidence that what is being witnessed across the Built Environment will likely increase and also that more advanced industries have experienced the same problems previously. It is therefore seen as a growth area for the Built Environment to reduce the impact of obsolescence and ensure that service delivery continues to meet societal expectations.

Keywords: *Asset Management, Lifecycle, Obsolescence, Service Delivery, Facilities Management*

1. Introduction

Since 1965 when Gordon Moore first speculated about the future trend of computational power, Moore’s Law, technology has continued to support this original foresight (Mack 2011). Regardless of the readers’ views upon privacy, data, statistics and the like, there is a wealth of literature both within the main stream circles and academic journals, illustrating the dramatic change we are all experiencing and the plethora of change to come. Every day in 2015 over 75% of UK adults use the Internet, for a variety of needs, with almost 100% of them using it ‘on the go' (Office for National Statistics 2015). These two statistics are more than double the uptake of 2006. Similarly, an independent report produced by the World Economic Forum in 2015 identified from a survey of 800 executives and experts, from the ICT sector, that by 2025 the first 3D printed production car would be on the road and the Built Environment would encapsulate 1 trillion sensors connected to the internet (World Economic Forum 2015). Much of the above can be found within literature associated with the term the ‘Internet of Things (IoT)’. IoT is founded upon the increasing computational power and reduction of cost and size of sensor technology (Moore’s Law), making the embedment of such technology financially viable on a large scale. In addition to the trends and developments made within industry, there are social implications of such change, Michael Felton of the New York Times created the diagram in Figure 1, which demonstrates the rapid increase of technology adoption in American households. This powerful illustration shows not only how technology is quickly finding itself within the home, but also how once a new form of technology has become accepted it quickly saturates. Technology trends such as the IoT offers a wide variety of benefits for both building occupants, through service delivery, and Facility Managers through data collection and analysis (please see Big Data, Predictive Analytics and Machine Learning).

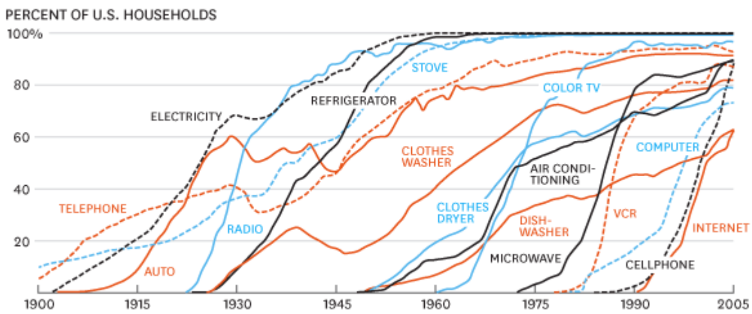

Figure 1 Technology Adoption within American Households, adopted from Felton (2008)

Gravier & Swartz (2009) described another side to the above trends and coined it ‘the dark side of the technology curve’, within which it was highlighted that obsolescence and lifecycle mismatches would carry significant operational and financial costs. Obsolescence occurs when a component or asset is no longer suitable for current demands or is no longer manufactured or supported. Obsolescence is not a new term, phenomena or problem, however in light of the above trends it is tipped to greatly effect the Built Environment in the same way it challenges the Oil & Gas, Avionics, Aerospace and Defence industries. This paper will draw upon new findings from a case study experiment, illustrating the cost of ‘the dark side of the technology curve’ within the Built Environment.

2. Literature Review

The following section will cover two key themes; recent trends around the IoT and the changing expectation of service delivery within the Built Environment, regarding asset obsolescence. The purpose being to capture the future changes that will effect our buildings and how we deliver services, and also the wider implications/demands upon lifecycling techniques and standards.

Depending on whether you reference MIT Technology Review, International Data Corporation (IDC) or business consultancy firm Gartner, forecasted projections of 28, 32 or 33 billion connected devices will exist by 2020 (SIEMENS 2014). Such an expansion of devices, both producing and collecting data, will become inevitably wide reaching. Google trends currently illustrate distinct search patterns, telling a story of how large sections of society are becoming actively aware of the IoT, shown in Figure 2.

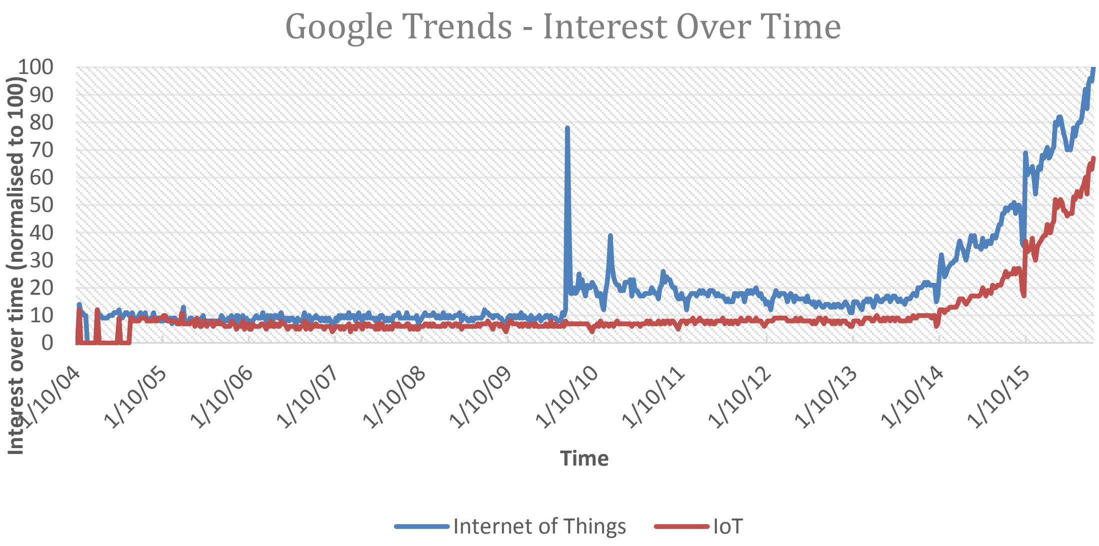

Figure 2 Google Trends for the terms 'IoT' and 'Internet of Things', publically available data from www.google.co.uk/trends/

In light of the above figure, it is felt by this author that such trends will effect society in both an active and passive way. Meaning, we as members of society will either actively adopt new services, now possible through big data analysis and the medium of smart phone applications for example. Alternatively, lives of some sections of society, will passively be effected by efficiencies, now possible through discrete optimisation modelling and data driven decision making, traffic flow for example. Ultimately however, as we have witnessed with the adoption of smart phone technology, once the concept has been accepted, it quickly becomes expected. Therefore, whether you actively or passively partake in the trends outlined within this paper, subconscious acceptance of new performance levels of service delivery is likely.

The above theory, aligns with the views of 'mutual shaping' with regards to 'social shaping of technology (SST)', where society and technology development are not independent of each other but rather influence and shape each other mutually (Williams & Edge 1996; MacKenzie &

Wajcman 1985). This is a contrasting view to the previously followed technology determinism views upon technology development, heavily associated with Karl Marx. SST directly tackles the conflict between technology development, in this context relating to the IoT, against societal values and expectation, in this context relating to privacy and service delivery expectations. Does technology development shape society? Or conversely will society shape the development of technology? Interestingly, Williams & Edge (1996) explain how the concept of SST involves the idea of 'choices' (though not necessarily conscious choices), meaning in a 'mutual shaping' context, society will consciously and subconsciously effect and be affected by technological change within the Built Environment.

In 2014, SIEMENS as part of their 'pictures of the future' magazine, reported that the Asia Pacific region were investing more into the IoT than Europe or North America, shown in Figure 4 (SIEMENS 2014). This mirrors the analysis undertaken by Google, in Figure 3, showing that six of the top seven countries searching for information regarding the IoT are from the Asia Pacific region. The result of such activity has led to these areas also holding both the largest number of and fastest growth rate of patents related to the IoT, typically linked with organisations such as LG Electronics and Samsung (LexInnova 2014).

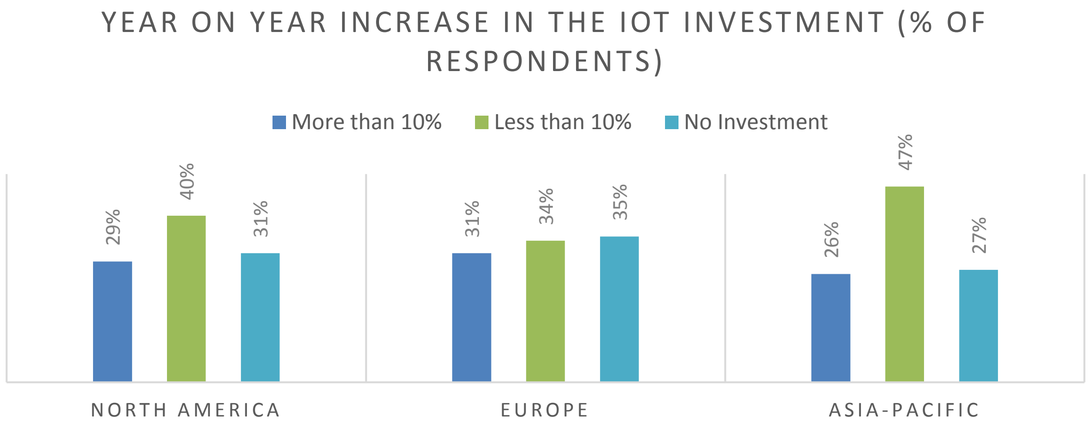

Figure 4 Year on year increase in IoT investment, percentage of respondents within report, adapted from SIEMENS (2014)

Figure 3 Google Trends of the terms 'IoT' and 'Internet of Things', publically available data from www.google.co.uk/trends/

The IoT is on course to disrupt and revolutionise the performance of FM service delivery, currently being capitalised by organisations located from the Asia Pacific region. This will inevitably effect society in both our professional and personal lives, potentially changing our expectations of service delivery within the Built Environment. There is academic and industrial evidence supporting the above relationships, however whether they are causal is yet to be clearly understood, therefore the real impact of such change upon both service delivery and society, is not well defined. This paper will now draw the readers' attention to the other side of the above trends covered within this literature review, focussing on obsolescence and the life sustainment issues created by lifecycle mismatches.

Obsolescence occurs within assets when they are no longer manufactured or supported, this occurs in both software and hardware, recently exacerbated by the explosion of the consumer electronics market and the resultant shortening of lifecycles (Feng et al. 2007; Solomon et al. 2000; BSI 2007). Solomon et al. (2000) produced Figure 5, which conceptually introduces how both obsolescence is inevitable and also time related. A single asset, or collection of assets within a system, will contain hundreds and often thousands of components, which will contain their own lifecycles. The length and profile of these respective lifecycles are dictated by market forces and manufacturers. This unknown characteristic of assets within the Built Environment, creates lifecycle mismatches, causing supportability issues for FM and building users. This predominantly unrecorded, side effect of technological advances was coined as 'the dark side of innovation' by Gravier & Swartz (2009). The case study featured within this report begins to quantify the scale of the impact of the aforementioned dark side. A bibliometric analysis, shown in Figure 6, illustrates the rising research attention towards obsolescence. However, following gap analysis it was identified that consideration for the assets found within the Built Environment, and end users as opposed to manufacturers receive little attention.

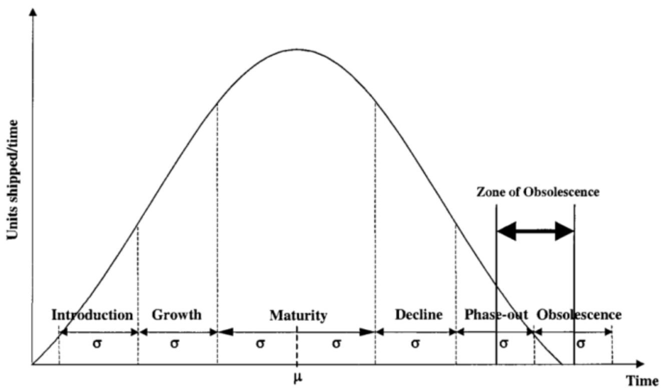

Figure 5 Obsolescence lifecycle stage, from Solomon et al. (2000)

The crux of obsolescence within assets, is the dependence upon life expectancy of assets and their components and the need to lifecycle cost the projected intended life the asset. This is further complicated by the BS ISO 15686-2:2012 for Service Life Planning of Buildings and Constructed Assets containing the following caveat:

"[Lifecycle Planning] ... does not cover limitation of service life due to obsolescence or other non- measurable or unpredictable performance states." - (BSI 2012) Service Life Planning

It is common practice to provide a nominal figure in years for the expected useful life of assets and major components, this prescriptive approach and has proven to be sufficient. This paper will challenge the applicability of such stationary methods for assets and asset systems that now experience dynamic variations of lifecycles and life expectancy as markets change at a faster rate.

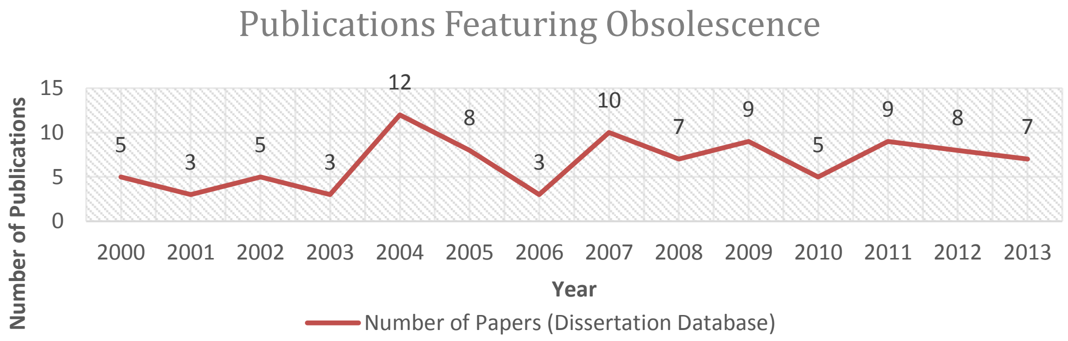

Figure 6 Bibliometric Analysis of Literature featuring keyword search: Obsolescence

In summary, there is evidence suggesting that the Built Environment as we know it, is to become digitised in the coming decade with an abundance of new data streams being created. Service delivery will experience dramatic improvements through the adoption of smart data analysis, providing tailored services to increase satisfaction of building users. Once wide spread, this is likely to become accepted as the norm and therefore a change in societal expectations upon service delivery by FM. In order to keep up with this trend and adopt further technology within our buildings, the effects of obsolescence are likely to increase, impacting both operationally and financially upon FM. It is logical, to therefore extract a need to improve obsolescence management techniques in tandem with 'dynamic' lifecycle methods to mitigate these effects both more precisely and strategically.

3. Research Design

This paper has adopted a case study design, using a UK based PFI funded London office building, which has a 100,000 m^2 foot print. This particular PFI was a refurbishment contract and the case study investigates into the effects of obsolescence into key long term asset systems. The time frame featured within this paper spans from 2010 to 2015, a decade on from practical completion of refurbishment works. A quant point to note, as the average life expectancy of software will predate this case study, whilst the 'mother' systems will require sustainment through and beyond this study.

Following discussions with the PFI contractor regarding historical procurement patterns and knowledge from the literature review, it was suggested that the following three systems be considered for this case study:

- Fire Alarm System
- Security System
- Building Management System

Historical purchase orders were analysed to investigate the pattern of investments, against the pre planned lifecycle expenditure for these systems. Specifically, any lifecycle investments associated with obsolescence were also extracted to begin formulating evidence to the scale of impact of obsolescence within this case study.

Further to the above data, meetings were held with the respective organisations involved within the supply and maintenance of the above systems to explore additional context. This qualitative element of this paper, adds to the numbers that feature within the discussion section.

In summary, it was felt a PFI funded piece of infrastructure was an appropriate case study, as it provided unparalleled access into commercial information, which if resided within the public sector would unlikely we available. PFI contracts also provide a set of constraints and drivers to optimally operate asset systems, whilst strategically planning their lifecycle replacement, creating further incentives for all stakeholders to understand the impact of obsolescence further.

3.1 Case Study Evidence

Figure 7 is a lifecycle budget for the case study site, spanning from 2005 to 2015, illustrating the annual planned expenditure to replace assets in a prescriptive manner. This projection, naturally is management by an Asset Manager and the profile can change if there are both unexpected failures of assets and unexpected expenditures. The highlighted bars show the focus of this case study, the period 2012 to 2015, where the three case study asset systems were investigated. Note, the profile of the lifecycle expenditure and how in the year 2013, around a decade on from refurbishment, considerable investment was planned. Whilst this has logical

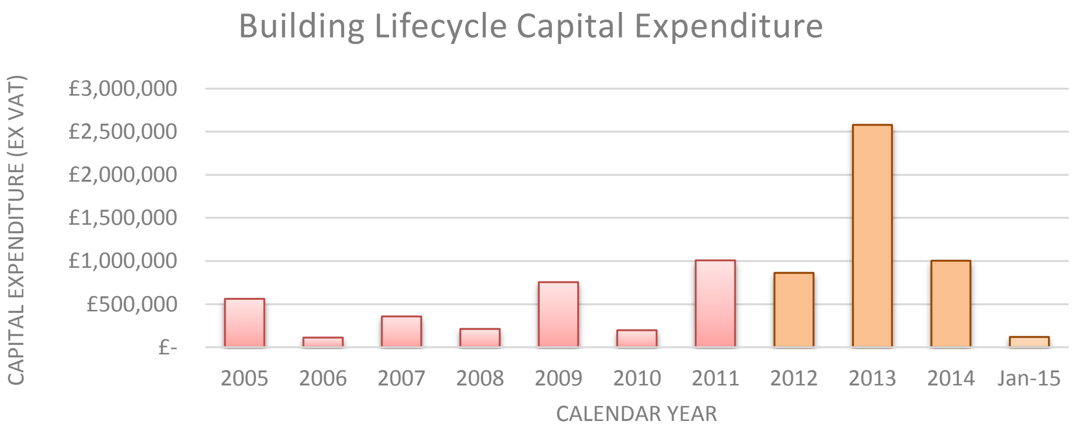

Figure 7 Building Lifecycle Capital Expenditure, across length of PFI to date

narrative, it is not data driven and it is not dynamic. The efficiency of a lifecycle fund is reliant upon the competence of the Asset Manager, and their ability to reactively reorganise programmes of replacement to offset costs.

In order to investigate the current impact of obsolescence driven investments, a snapshot of the time frame 2012 to 2015 was taken and then illustrated in Figure 8. As you can see across this short period there were considerable investments related to obsolescence (~ £1.5m). Note, it is not solely the financial size of these investments which can pose a problem for lifecycle management, but the unforeseen nature of the majority of these investments. Requirements that did not exist prior to their identification can put pressure on FM and the operational business of service delivery. Evidently, there are financial drivers to research into the management of obsolescence and lifecycling techniques, however, it is the operational impact in life critical environments i.e. major hospitals that prove to be the overriding driver.

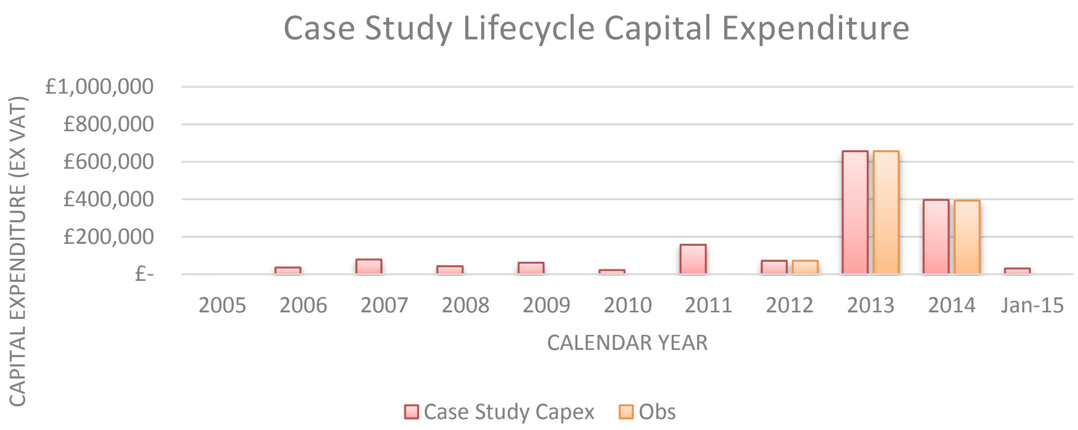

Figure 8 Case study comparison of obsolescence related investments and individual lifecycle expenditure

Mining the data further, two things were discovered; firstly, within the case study asset systems 10 years on from installation, 90%+ of the annual lifecycle expenditure was driven or associated with obsolescence, shown in Figure 8. Evidence that the effects of obsolescence may be cyclical

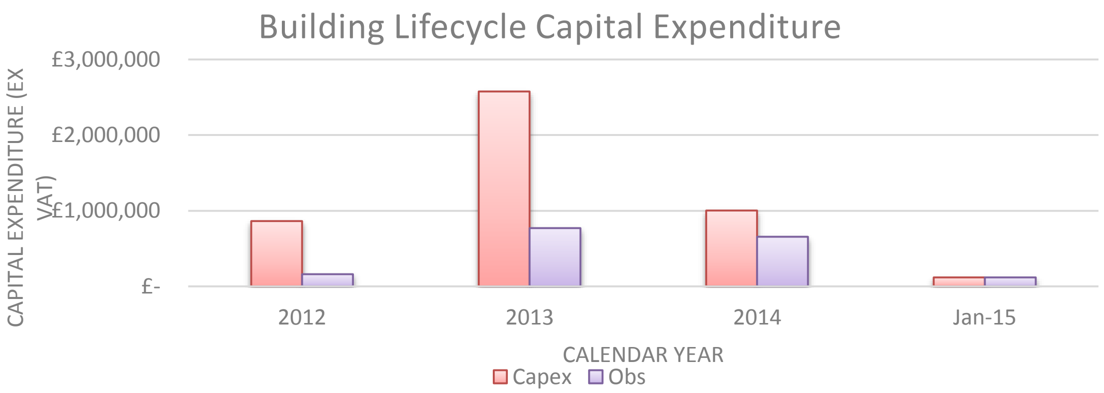

Figure 9 Case study obsolescence associated investments compared to total lifecycle expenditure for entire site

in behaviour. Figure 9 illustrates the total annual lifecycle expenditure across all systems, across the same period, 44%, 85% and 60% of the expenditure related to obsolescence was found within the three case study systems. Evidence, that the 80:20 rule is likely to apply, important when seeking to strategically manage obsolescence within the Built Environment.

In summary, the evidence provided by this case study have speculated that obsolescence may behave in a cyclical fashion, occurring in a repeated manner. Also, the Fire Alarm System, Security Systems and Building Management System are likely to concentrate your obsolescence driven investments and if only limited resource are available, to focus them on these assets. Finally, there is sufficient evidence to demonstrate that obsolescence is effecting the Built Environment currently and if managed reactively, can create significant additional lifecycle expenditure, which can cause both operational issues and lifecycle management issues.

4. Discussion

In the UK BS 8544:2013 for 'Guide for life cycle costing of maintenance during the in use phases of buildings', is widely used, it details the methodology for lifecycle costing (LCC) of maintenance for in use phase assets (BSI 2013). The methodologies encompassed by this British Standard, whilst comprehensive have two fundamental weaknesses. Firstly, due to their prescriptive nature, the effectiveness of LCC is dependent upon the competence of the individual performing the methodology and their respective experience and knowledge. In practice, it is common for this individual to change over time and for information sharing or continuity planning to fail. Secondly, the information gathered in the 'capture stage' of asset LCC must remain 'live' or dynamic in order to be applicable to the real world situation. In practice, it also not uncommon for this requirement to not be robustly implemented, therefore classifying the data being used for LCC obsolete or out of date. However, a competent and experienced Asset Manager may still posses the knowledge required to effectively manage assets through their lifecycle, maintaining their operational status.

This paper draws upon several major trends that when implemented will drastically shorten the lifecycle of many, previously long life, asset systems. This shortening will encourage obsolescence and reduce the time available to manage and plan asset maintenance. These aforementioned forces, will require a more dynamic approach to LCC, that is more flexible to sudden changes in market conditions, deeming specific component(s) obsolete, effecting useful life supportability.

The case study that features within this paper highlights how, within one example, current Asset Management practices are failing to avoid obsolescence driven investments. This has driven additional lifecycle costs and also applied short term operational risks to the organisation. Ultimately, this paper seeks evidence to suggest that the current practice for LCC should be readdressed, in order to avoid what Thomsen et al. (2015) label as 'obsolete buildings'; where building demands have changed and service delivery has failed to adapt. A recent example of the impact this can have upon the Built Environment could be, the changing buying behaviours of UK supermarket shoppers. The Financial Times reported that British Supermarkets are to write off billions of pounds from the value of their supermarkets, due to consumers shifting their preference to smaller outlets and online shopping, deeming the large style supermarket as a business model obsolete (Grover & Grover 2012).

4.1 Need for Dynamic Lifecycling

The term 'dynamic' in this paper refers to a method that is flexible and adaptive to characteristic changes. For example, a LCC method that considers obsolescence throughout the useful life, proactively monitors performance and condition deterioration, whilst amending the expected life and lifecycle replacement strategy would be considered flexible. In other pieces of literature this type of decision making model, have been described as 'data driven' as opposed to an 'expert system'.

Academic literature by Bradley & Guerrero (2008), Sandborn (2013), Feng et al. (2007), Gravier & Swartz (2009) and many others, all suggest that the impact of obsolescence is only going to increase. These thoughts were echoed by those decision makers within the aforementioned case study, who were witnessing it's effects first hand. If current methods remain stationary, whilst the trend of obsolescence risk increases, then the shift to meet growing societal expectations in the future will be a costly one.

Finally, to illustrate the possible future impact of obsolescence driven investments within the case study that features within this paper, Figure 10 was created. To create Figure 10, an assumption was made on the behaviour of obsolescence within long life asset systems, that lifecycles of components within systems across a building were so miss-aligned that obsolescence driven investments would occur on an almost annual basis in various systems. This would be represented on a lifecycle budget projection as a random/constant percentage of the annual expenditure. In order to project these percentages, the case study profile was extrapolated across the remainder of the PFI contract and visualised as a percentage of the actual planned lifecycle budget for this building.

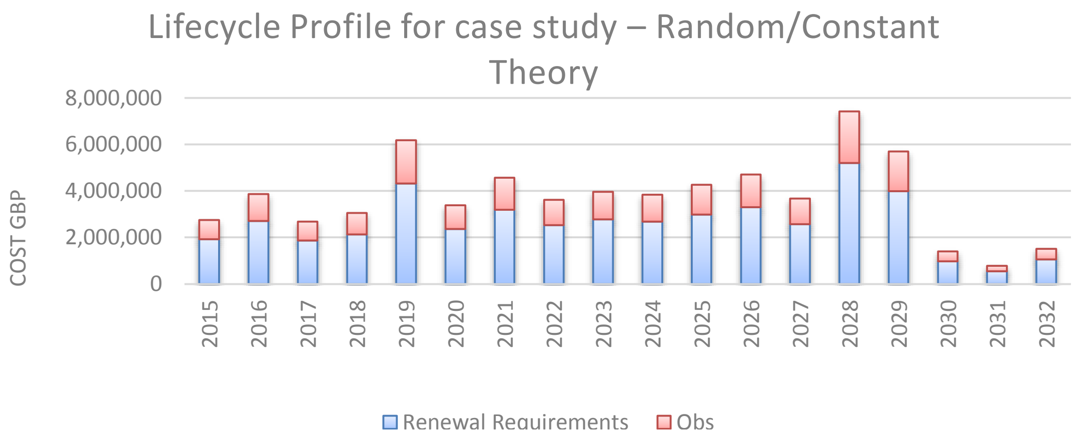

Figure 10 Extrapolated future obsolescence related investments as a percentage of planned Lifecycle expenditure for remainder of PFI

The accumulative investment associated with obsolescence for this single PFI contractor is potentially staggering. By 2032 an additional total of £20 million could be assigned to obsolescence related investments. Note, what this projection does not account for, is whether these investments are in addition to the current lifecycle planned expenditure or inclusive. This is unknown due to the timing of an obsolescence driven investment, which will massively impact an Asset Manager's ability to offset other planned lifecycle expenditures to keep the annual within budget.

5. Conclusion

To conclude, we refer back to the title of this paper 'changing societal expectations and the need for dynamic asset lifecycling and obsolescence management' and cover the key trends and points made.

In 2015 now more than half of the planet now live within cities, creating a dense urban environment. Researchers across academia and industry are both seeking to implement new technology to create new methodologies for service delivery across the Built Environment, in a way that previously was not possible, advances in this area come under the umbrella of the IoT.

History has shown us that whilst it is unclear whether society shapes technology, or vice versa, it is clear that as soon as technology is commercially accepted, it quickly becomes expected. It has been speculated within this paper that when FM actively embraces the IoT and provides new levels of service delivery, building occupants will quickly adopt and expect a consistent new service level.

The IoT has the potential to improve service delivery in almost every context, however this paper dives deeper into the 'dark side' of technological advancement and the cost of obsolescence when seeking to support asset systems within the Built Environment. Connected to obsolescence are the current LCC methods, which have proved to be sufficient in modern construction. The case study that featured within this paper has provided some evidence that the cost associated to obsolescence is significant and growing. The reactive manner in which obsolescence is currently managed and its current separation from the LCC methodology, has created a demand for a more dynamic approach, which is likely to be more data driven. This paper features some work from a current Engineering Doctorate research project, which is developing and testing data driven decision and risk tools for mitigating obsolescence.

Finally, whilst this paper illustrates a single case study which may not be homogenous across the industry, if academia is to be believed and the risk posed by obsolescence is only to increase and the industrial research on modern trends are to be believed. Then we need to adapt our methods now, in preparation for the changes we are all going to witness in both our personal and professional lives.

The Role of Leadership and Organizational Climate in Fostering Innovation in Construction

Isabelle Y.S. Chan, Anita M.M. Liu

Department of Real Estate and Construction, University of Hong Kong, Hong Kong
Email: iyschan@hku.hk

Abstract

Leadership has been identified by many researchers as one of the most important antecedents of innovation. Previous studies tend to conclude that transformational leadership, through motivating followers to change their status quo, has a higher positive impact on organizational innovation when comparing with transactional leadership. However, the relationships between transformation leadership and innovation are inconsistent. These contradictory findings, to certain extent, suggest that the influences of leadership on innovation can be influenced by various mediators, such as innovation climate in an organization. Leaders foster innovative behaviours of followers by creating a climate that facilitates the innovative activities through, for instance, forming organizational routines to assist in achieving innovation. This organizational climate, in turn, influence the impact of leadership on innovation. Innovation has found to be essential in enhancing work effectiveness, efficiency, and business performance in the construction sector. However, hindered by various factors, construction has long been recognized as low in innovation. Success of innovation requires intimate collaboration between multiple stakeholders in developing innovation blueprint and sustaining commitment towards innovation in technically complex areas. However, due to the different value propositions amongst organisational members, tension may arise, which affects the collaboration. Hence, this study aims to investigate the mediating effects of organizational innovation climate on the leadership-innovation relationships. A questionnaire survey is designed which adopts: i) the multifactor leadership questionnaire for assessing the perceived leadership style, ii) the innovation culture scale, and iii) the innovation scale for measuring the ability of an organization to innovate as perceived by followers. The relationships are tested by factor analyses, reliability analyses, correlation analysis, and multiple regression modelling using SPSS and Lisrel. Seven factors are identified, including charisma, intellectual stimulation, individualized consideration (transformational leadership) and contingent reward (transactional leadership) for leadership; support for innovation and resource supply for innovation culture; and innovation performance. The findings reveal that support for innovation plays a significant mediating role on the influences of both transactional and transformational leaderships on innovation. The results of this study lay solid platform for further longitudinal, qualitative studies for the dynamic intertwining relationship between leadership and innovation culture across the organizational innovation process.

Keywords: Construction, Innovation, Leadership, Organizational Climate

1. Introduction

Success of innovation requires intimate collaboration between multiple stakeholders in developing innovation blueprint and sustaining commitment towards innovation in technically complex areas. Due to the different, or even competing, value propositions amongst the stakeholders, tension may arise, affecting the collaboration (Adner, 2012). Therefore, leadership has been identified by many researchers as one of the most important antecedents of innovation (e.g., Amabile, 1998; Jung et al., 2003). While extant research tends to contribute useful insights into the associations between leadership and innovation, its ability to guide management practice is limited by the predominance of studies which focus on leaders' behaviours and on transformational leadership in particular. Although understanding how transformational leadership influence follower's creative behaviours is worthwhile, a more important concern for organizational leaders is how to lead organizational innovation across different situations and environment.

Leadership, such as leaders' psychological states and behaviours, are personal characteristics of a leader. A type of leadership effective in one situation /environment may thus not be in another (McLaurin, 2006). According to Fiedler's *contingency theory* (1972), the effectiveness of team performance is contingent upon two factors, namely the motivational pattern of a leader and the contextual factors which empowers a leader. Motivational pattern mainly refers to the leadership types of a leader, such as task-versus-relationship oriented leadership (Miller et al., 2003) and transformational leadership (Carter, et al., 2014); while contextual factors are referred as situational favourability which determines the degree to which a situation [e.g., organizational climate (Haakonsson et al., 2008)] allows the leader to have power and influences tasks (McLaurin, 2006). Hence, based on the central assertion of contingency leadership theories, this paper proposes that the relationship between leadership and innovation of followers are contingent on an organization's innovation climate.

2. Leadership and Innovation

One of the first researchers in the field of innovation was Schumpeter in 1934 who defined innovation as "the commercial or industrial application of something new – a new product, process or method of production; a new market or sources of supply; a new form of commercial business or financial organization" (see Stone et al., 2008; p.II-2). The definition evolves along the development of innovation research. Summary of extensive literature suggests that innovation can be defined as a process of "generation, development and implementation of ideas" (e.g., Dulaimi et al, 2005; p. 566) in different forms (e.g., product, process, marketing and management innovation), which are new (i.e., "novel to the institution" (Slaughter, 1998; p. 226)) and are expected to yield enhanced value (i.e., "reduction in cost and/or time associated with project delivery and improve the quality of outcomes" (Kissi et al., 2012; p. 12)). Grounded on the above broad definition, various typologies of construction innovation are identified, such as radical versus incremental innovation, bounded versus unbounded innovation, and 'hypercube' of innovation (Harty, 2008).

However, different types of innovation work in conjunction. More importantly, innovation has to evolve so as to convert the ever-changing business challenges into opportunities. In the complex socio-economic environment where an organisation needs dynamic capabilities and competencies to solve challenging tasks, innovation competence (which constitutes a type of dynamic capability) is a crucial factor (Teece and Pisano, 1994). While creativity is often referred as the source of innovation (e.g., Amabile, 1998), the ability of an organisation to create novel design, construction, management and/or service delivery approaches in the competitive industrial environment is typically dependent on individuals' domain of knowledge and capability. More importantly, competency is a key element predicting performance of construction professionals (Dainty et al., 2005) and the inability of construction parties, clients and clients' agents to adopt or absorb innovations generated by other stakeholders (e.g., contractors or consultants) hinders innovation in construction (Manley, 2006). Innovation competency governs the innovation behavior of individuals and is defined as the disposition of individuals "to act and react in an innovative manner in order to deal with different critical incidents, problems or tasks that demand innovative thinking and reactions, and which can occur in a certain context" (Cerinšek and Dolinšek, 2009, p.166). In this study, innovation competency, which can endure for a reasonably long period of time in a construction firm, is used to examine the ability of its employees to innovate in various forms to enhance performance and competitiveness at organizational levels.

Leadership has been identified as one of the most essential antecedents of innovation (e.g., Amabile et al., 2004; Mumford et al., 2002), which influences not only individual creativity but also organizational innovation (e.g., Gumusluoglu and Ilsev, 2009). Leadership, as an instrument of goal achievement (James et al., 2007), has been identified as a convergent process that acts on both organizational culture and individual behaviors (Ostroff et al., 2003). Based on the organizational goals and values perceived by a leader from the organizational culture, s/he puts intentional efforts into influencing and aligning the values, visions and behaviors of followers with that of the organization. The fundamental function of leadership for innovation is to facilitate interpretations of followers by providing meaning, to enable followers to generate, interpret and implement innovative ideas in a manner that ensures alignment with organization's mission (Berson et al., 2006). In this process, leadership and the organizational climate are entangled.

According to Bass and Bass (2008), leadership refers to "an interaction between two or more members of a group that often involves a structuring or restructuring of the situation and of the perceptions and expectation of the members...directing the attention of other members to goals and the paths to achieve them" (p.25). Transformational and transactional leaderships are the two main types of leaderships identified in the literature, in which transformational leadership refers to leaders whose focus is in fostering the higher order intrinsic needs of followers, in preference to immediate self-interests, through idealized influence (charisma), intellectual stimulation, or individualized consideration, while transactional leadership refers to leaders whose focus is in establishing an exchange-based relationships with followers through rewarding goal achievement (Bass and Avolio, 2004). Previous studies tend to conclude that transformational leadership, through motivating followers to change their status quo (Keller, 2006), has a higher positive impact on creative climate and organizational innovation when comparing with transactional leadership (e.g., Jung et al., 2003, Elenkov and Manev, 2009).

However, the relationships between transformation leadership and innovation are *heterogeneous* (i.e., correlations ranging from positive to negative) (e.g., Basu and Green, 1999; Shin and Zhou, 2003). These contradictory findings, to certain extent, suggest that the associations between leadership and innovation are *contingent* and that these associations can be influenced by various moderators, such as organizational climate [e.g., support for innovation (Jung et al., 2008) and climate for excellence (Eisenbeiss et al., 2008)]. In this study, the moderating effects of innovation climate on the leadership-innovation relationships are investigated.

3. Organizational Innovation Climate

The sociological approach to creativity takes the view that both the level and the frequency of creative behaviours are influenced by the social environment (Woodman et al, 1993). Following this theme, climate can be defined as a psychologically meaningful description of the work environment (James and Jones, 1979), and "a set of attributes specific to a particular organsiation that may be induced from the way the organsiation deals with its members and its environment" (Campbell et al, 1970, p.390). "For the individual member within an organsiation, climate takes the form of a set of attitudes and expectancies which describe the organization in terms of static characteristics … and behavior-outcome and outcome-outcome contingencies".

According to Scott and Bruce (1994), a climate for innovation can be conceptualized as support for innovation and supply of resources. Support for innovation refers to an organization which not only supports employees in pursuing new ideas, but also tolerates diversity among them (Siegel and Kaemmerer, 1978). Change is essential to the development and implementation of any innovative ideas (Poole and Van de Ven, 2004). Through managing changes in policy, procedures (i.e., first-order changes) or changes of fundamental organizational assumptions, like vision and core values (i.e., second-order changes) properly, an organization evolves (Rothwell et al., 2010; Wang and Sun, 2012). On the other hand, although diversity between employees may induce workgroup conflicts and decrease work efficiency, it is important to organizational innovation (Florida and Gates, 2003; Milliken and Martins, 1996; Scott and Bruce, 1994). It is because only employees with tolerance of diversity can be open-minded to new or improved ideas at work (Anderson and West, 1998). In addition, to nurture a group of creative employees, organizations should supply adequate resources, such as time, human resources, material, management support, so as to allow them to pursue innovation at work (Kesting and Ulhoi, 2010).

Support for innovation climate "reflects collective perception among team members that their collaborative, innovation-related activities are expected, valued and supported in the team" (Chen et al, 2013:1020). It enables members to innovate effectively by promoting a more collaborative environment whereby team members assist, support and coordinate with each other in their attempts to innovate (Chen et al, 2013). According to West (1990), higher levels of support for innovation climate motivate individuals to initiate and persist in innovative behaviours and transformational leadership fosters innovation through support for innovation by encouraging members "to collaborate and to assist each other with idea development and implementation" (Eisenbeiss et al 2008:1440). Hence, the association between leadership and innovation performance can be affected by innovation climate.

A transformational leader has the ability to arouse and change members' propensity for longer-term and more creative perspectives (Bass and Avolio, 2004), that is the leader stimulates members' efforts to be innovative by questioning their assumptions, reframing problems and approaching situations in new ways. At the same time when transformational leaders internalize the organizational climate /culture for innovation through sensemaking, their externalization of this sensemaking shapes the organsiational climate /culture of followers, resulting in followers valuing creative thought processes and innovative work approaches (Jung et al, 2003). Since organisational climate and culture represent collective social construction (Mumford et al, 2002), they serve as a sense-making device and guiding principle for more innovative work processes that could ultimately lead to innovative performance in terms of new products and services (Scott and Bruce, 1994).

4. Research Method

Based on the above, quantitative method based on questionnaire surveys is employed to test the hypothesized relationships using correlation analysis, regression modelling and structural equations modelling. Questionnaires of this study are equally distributed to 500 respondents from different organisations of client developers, construction consultants, and contractors in China. Both purposive sampling and convenience sampling are used. Data are returned from 158 respondents (31.6% response rate) via email, web-based questionnaire system, fax return, and face-to-face meeting. There is a good mix of respondents from different professional disciplines (34.8% project management, 16.5% architecture, 15.2% structural engineering, 13.9% quantity surveying, 8.2% building services engineers, and 11.4% others) and management levels (46.1% middle management, 29.8% professionals, 19.5% senior management, and 4.5% others). There are 73.4% of respondents who have amassed more than 5-year experience in the organization (36.7% more than 15 years, 25.3% 11-15 years, 20.3% 1-5 years, 11.4% 6-10 years, 6.3% less than 1 year).

The questionnaire has three main parts: i) the multifactor leadership questionnaire (MLQ) scale (Avolio and Bass, 2004), ii) the innovation climate scale (Scott and Bruce, 1994), and iii) the innovation scale (Kaiser and Holton, 1998). Respondents are asked to rate their responses in 5 point Likert measurement. To further confirm the factor structures in the current study which target the construction sector, confirmatory factor analysis is conducted to justify the validity of the factor structures of:- transformational and transactional leadership (i.e., charisma, intellectual stimulation, individualized consideration and contingent reward), innovation climate (i.e., support for innovation and resource supply), and innovation. Confirmatory factor analysis aims to test and confirm specific hypotheses concerning the structure underlying a set of items (Pallant, 2005).

The analyses are conducted by structural equation modelling using Lisrel 8.7. Although four fit indices are usually suggested to quantify the degree of fit of a structural equation model (Kline

1998), six fit indices are included in the current analysis. The resulted model fit indices are satisfactory, in which the relative chi-square values (x^2/df) are between 2 and 5 (good model fit; Diamantopoulos and Siguaw, 2000); the values of root mean square error of approximation (RMSEA) are lower than 0.08 (a reasonable model fit; Bollen and Long, 1993); the comparative fit indices (CFI); the goodness of fit indices (GFI); and the relative fit indices (RFI) are higher than 0.8 (the closer to 1, the better the model fit; Diamantopoulos and Siguaw, 2000). Meanwhile, the Cronbach's alpha value of each factor is above 0.6, indicating acceptable reliability (Hair et al., 1998; Pallant, 2001).

5. Results

The correlation results indicate that innovation is correlated positively with all leadership and innovation climate factors, including charisma, intellectual stimulation, individualized consideration, contingent reward, support for innovation, and resource supply, at $p<0.01$ significance (refer to Table 1). The results also indicate that all leadership factors are significantly and positively correlated to support for innovation and resource supply at $p<0.01$ significance, acting as support to the moderating effect of innovation climate on the leadership-innovation relationship.

Table 1: Correlation between Innovation Climate, Leadership, and Innovation

Factors	LD1	LD2	LD3	LD4	IC1	IC2	INN
Leadership							
Charisma (LD1)	1	-	-	-	-	-	-
Intellectual stimulation (LD2)	0.769**	1	-	-	-	-	-
Individualized consideration (LD3)	0.741**	0.710**	1	-	-	-	-
Contingent reward (LD4)	0.657**	0.686**	0.703**	1	-	-	-
Innovation Climate							
Support for Innovation (IC1)	0.571**	0.498**	0.498**	0.486**	1	-	-
Resource supply (IC2)	0.562**	0.556**	0.563**	0.542**	0.774**	1	-
Innovation (INN)	**0.432****	**0.428****	**0.381****	**0.406****	**0.695****	**0.664****	**1**

To investigate the moderating effect of innovation climate on leadership-innovation relationships, hierarchical regression analysis is performed using pairwise deletion (Aiken and West, 1991). Two models are developed for the moderating effects of the innovation climate variables [i.e., support for innovation (Model 1) and resource supply (Model 2)] (refer to Table 2). In the first step of each model, the four leadership variables are added. In the second step, the moderators are added. Subsequently, in the final step, the interaction terms of the moderators and the four leadership variables are added to test the hypotheses. The values of R^2, adjusted R^2 and significant F change are shown at the bottom of each model. Only support for innovation (ICI1) is found to have significant moderating effect (sig. F change < 0.05 as shown in Model 1).

Results show that before taking the interactions into account, the four leaderships are not significantly associated with innovation, indicating that the influences of leaderships on innovation are not simple straightforward effects. Support for innovation (IC1) is positively

Table 2: Hierarchical regressions

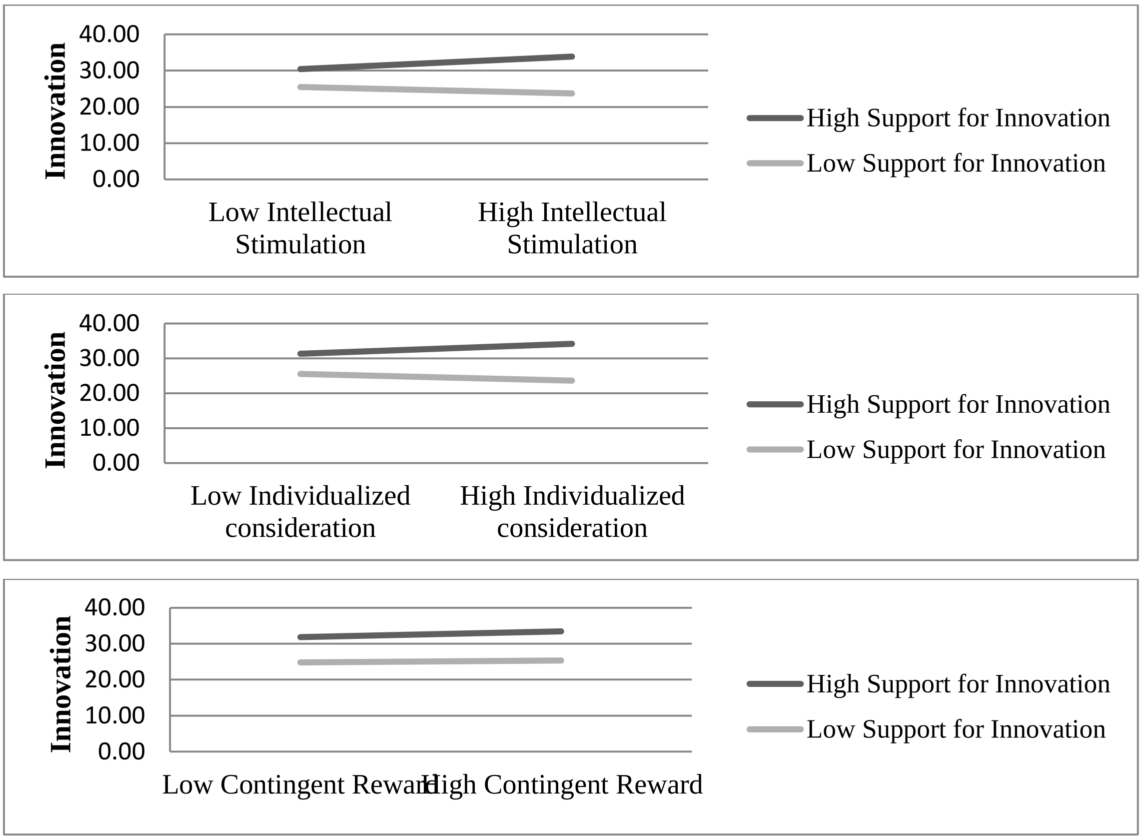
R^2 *(Step 1)* / ΔR^2 *(Steps 2-3)*	0.472		0.229		0.042	
Sig. F Change	0.000		0.000		0.190	

Note: * $p<0.05$; ** $p<0.01$

related to innovation (Step 2 of Model 1). However, after the interactions are taken into account (step 3 of Model 1), the influence of IC1 on innovation becomes insignificant. The interaction model containing IC1 as moderator of the four leaderships significantly adds value to the final model, in which the interactions of IC1 with intellectual stimulation (LD2 x IC1), with individualized consideration (LD3 x IC1), and with contingent reward (LD4 x IC1) on innovation are significant (Step 3 of Model 1).

Results show that before taking the interactions into account, the four leaderships are not significantly associated with innovation, indicating that the influences of leaderships on innovation are not simple straightforward effects. Support for innovation (IC1) is positively related to innovation (Step 2 of Model 1). However, after the interactions are taken into account (step 3 of Model 1), the influence of IC1 on innovation becomes insignificant. The interaction model containing IC1 as moderator of the four leaderships significantly adds value to the final model, in which the interactions of IC1 with intellectual stimulation (LD2 x IC1), with individualized consideration (LD3 x IC1), and with contingent reward (LD4 x IC1) on innovation are significant (Step 3 of Model 1).

To determine the nature of the above interactions, simple slopes are established for the significant interaction resulted in Table 6 (Aiken and West, 1991) (refer to Figures 1a-c). Under high support for innovation (one standard deviation above the mean), high intellectual stimulation and high individualized consideration foster innovation, while under low support for innovation (one standard deviation below the mean), vice versa. Under both high and low support for innovation, the higher the contingent reward, the better the innovation; while the degree of innovation is still higher under high support for innovation.



Figures 1a-c: The interactions between leadership and support for innovation on innovation

6. Discussion

Previous research on leadership and innovation tends to investigate transformational leadership as a whole (e.g., Bass et al., 2003; Pieterse et al., 2009), while inadequate focus has been put on the multi-dimensional nature of transformational leadership. Theoretically, transformational leadership composed of different factors, including charisma, intellectual stimulation and individualized consideration (Avolio and Bass, 2004). The different effects of these sub-factors on performance and innovation have been indicated. For instance, in Howell and Avolio (1993)'s study on business performance, charisma and intellectual stimulation are found to have positive impact on performance, while individualized consideration are found to have negative impact. In addition, Elenkov and Manev (2009) indicate that the interactions with sociocultural factors, such as power distance and uncertainty avoidance, change the influences of intellectual stimulation and individualized consideration on innovation from positive to negative and positive respectively. The results of this study further provide evidences that transformational leadership should not be considered as a whole. Under the interaction of support for innovation, transformational leadership of intellectual stimulation and individualized consideration have significant influences on innovation.

On the other hand, previous studies tend to conclude that transformational leadership fosters followers' creativity and innovation performance, while transactional leadership hinders them (e.g., Jansen et al., 2009; Jung et al., 2008). However, the results of this study indicate that contingent reward, a type of transactional leadership, has positive relationship with innovation under both high and low support for innovation. The higher the support for innovation, the higher the level of innovation is under the same level of contingent reward. Contingent reward leadership influence innovation through inducing compliance (Yukl, 2002). Followers carry out leaders' orders to obtain agreed awards. Thus, contingent reward leadership rely on open communication, which is important for innovation (Kickul and Gundry, 2001). Under high support for innovation climate, organizational members have higher strength on the values of innovation behaviours, which smoothen the process of communication for reward for innovation.

Transformational leadership does not necessarily foster innovation. Negative relationships are found between intellectual stimulation and innovation under low support for innovation. Intellectual stimulation leaders stimulate followers to rethink the ways they perform their works and engage in problem-solving activities in which new ideas may be resulted from the process (Bundy, 2002; Rafferty and Griffin, 2004). However, under the climates of low support for innovation, followers may not value creative ways of doing things. The intellectual stimulation of leaders can be conflicting to what the followers interpret from their environment, resulting in confusion, worries and concerns, which worsen their performance. Similarly, negative relationship is also found between individualized consideration and innovation under low support for innovation. Leaders applying individualized considerations respect and concern about follower's personal needs and development (Bass and Avolio, 1994). With leaders' understanding and support, followers are more willing to respond to change (House and Mitchell, 1974), which is essential for innovation. However, under the climates of low support for innovation, the perception that change is not valued prevails amongst followers, and that role conflict may occur between the perceived innovation climate and the individualized innovation stimulations from leaders, hindering innovation.

The results of the current research, conducted using quantitative methods, provide a foundation to examine the hypothetical relationships. However, quantitative methods attempt precise measurement of variables, while qualitative methods aim at seeking how and why things happen (Cooper and Schindler, 2006). The quantitative analysis results have not provided insights on what contribute to the differences in the associations between leadership and innovation under moderations, and why. Meanwhile, the study results are made based on sample from China only. Previous studies have indicated the influence of national culture on organizational climate and management (e.g., Hayton et al., 2002; Testa, 2009). To achieve an in-depth understanding of the leadership-innovation relationships and the moderating effects of innovation climate, it is recommended that qualitative, longitudinal research methods be adopted in further research to investigate the influence of national culture on organizational climate, leadership and innovation at organizational level worldwide.

7. Conclusions

Previous studies tend to indicate transformational leadership as an important determinant of innovation, over transactional leadership. However, evidence to this effect has been inconsistent. The results of this study unveiled one of the possibilities for the inconsistency through identifying the moderating effect of support for innovation climate on the leadership-innovation relationships:- i) Intellectual stimulation leadership is associated with increased innovation when support for innovation climate is high; ii) individualized consideration leadership is associated with increased innovation when support for innovation climate is high; and iii) the positive relationship between contingent reward and innovation can be found under both high and low support for innovation, even though the degree of innovation is higher under high support for innovation. Previous studies have investigated the influence of national culture on organizational climate and leadership. The results of this study, based on the sample from China, lay ground for further studies to investigate the relationship between innovation climate, leadership and innovation in the construction sector worldwide.

Abstract

The estimation of the next ten years, buildings will become the main reason of resource depletion. The energy consumption of global commerce and residential buildings will be responsible for nearly half of total consumption. Not only does the building process require energy consumption, the daily operations and maintenance of facilities will consume large amounts of resources. To solve issues of high energy consumption and high maintenance costs of the buildings, intelligent analysis methods are now used to increase overall efficiency. The operation models of intelligent buildings encompass many variables, so further research is required to understand the effects of the different factors and characteristics. By combining the various measurement standards and data, a more effective intelligent building operation model may be established to isolate the relativity of the physical environment and humans' biological effects, and through striking a balance between the physical and biological variables, the optimal operation model for intelligent buildings may be found and allow for the achievement of comfort and maximum environment benefits with the least amount of consumption. In the intelligent buildings, there will be many products and facilities dedicated to the comfort and health of the users, hence improvement of system efficiency and optimal operation model is based on the basic requirements of the users. The primary objective of this study is to use the building management mindset to analyze, through scientific means, the interactions and effects of "health", "comfort", and "energy efficiency" in intelligent buildings. Therefore, this study hopes to maintain the current conditions of indoor environment quality and comfort and establish "An Optimal Intelligent Building Operation Model" and conduct research and verification on case studies that have obtained the Taiwan Intelligent Building Labels.

Keywords: Intelligent building, Optimal operation model

1. Introduction

In order to promote sustainable development, energy-saving and carbon reduction of buildings, as well as to lead industries to innovate and integrate, the Executive Yuan established National Council for Sustainable Development Network in 1995. The first Green Building evaluation system in Asia, EEWH system (Ecology, Energy saving, Waste reduction & Health) was then developed based on the regulations on energy conservation in Taiwan. In 1999, the Architecture and Building Research Institute, Ministry of the Interior propelled the National Council to set up *The Evaluation Manual for Green Building*. The indicators were Greenery, On-site Water Retention, Daily Energy Efficiency, Carbon Reduction, Waste Reduction, Water Resource, Sewage and Garbage Improvements. In 2002, the Biodiversity Indicator and Interior Environment indicators were included to form the nine major indicators of the current Green Building Evaluation System.

Meanwhile, the Architecture and Building Research Institute, Ministry of the Interior was also conducting researches on Smart Living Space. After over ten years of researching since 1992, the Institute carried out the standard of quantification evaluation and instruction of standard operation based on the Intelligent Building Evaluation Index in 2003. The Institute established the Intelligent Building Evaluation Manual and started to accept the applications of Intelligent Building Evaluation Index. The Executive Yuan then continued to promote intelligent building and the industrial integration of ICT (Information and Communications Technology). In 2010, A new version of the Intelligent Building Evaluation Manual was established which included the eight major indicators of Unified wiring, Information and Communication, System Integration, Facility Management, Safety and Disaster Prevention, Health and Comfort, Convenience and Friendliness and Energy Efficiency and Management. The grading system of Intelligent Building Label and Green Building Label both identify five grade levels as follow: Diamond, Gold, Silver, Bronze and Qualified.

The industrial innovation center (IIC) in central Taiwan is the first building grading Diamond in both Intelligent building label and Green building label. The main purpose is to enter central department of Industrial Technology Research Institute and two foundations in institute of information industry information. By constructing advanced detection analysis simulation and high-level research lab, the operation between open lab and incubator were connected in order to assist central Taiwan promote technology innovation ability. The plan includes three main topics such like advanced greenhouse systems, smart devices and sense-based design.

Although we can now develop automatic and intelligent building with the advances in ICT industry, in this Era of Big Data, we can make use of the giant data base which is built up automatically or semi-automatically during the operation process to store, transform, analysis and calculate data. The data can then be applied in technology to develop a more efficient intelligent system of building. It may even help develop a technology that people can manage the building and city through the cloud with a simple device to enjoy a smart living in the future.

Taiwan is located in a subtropical zone and the latitude range of the South and the North is only around three degrees. Yet, the geographical environment and climate of Taiwan are varied. All regions are faced with different environmental issues which need different solutions. In addition to giving the priority to human health, an environmental quality which the users feel comfortable is necessary. Strategies appropriate to the local conditions and optimized operating mode of intelligent building should also be developed to achieve energy conservation of air condition, illumination system, acoustic and mechanical such facilities.

It should also be considered that if the degrees of the intelligence of building and energy saving are in a direct proportion, and if the benefits of intelligent system to the users are greater than the operating cost as well as the damage to the system's life cycle. Most of the equipment brings damage to the environment during the production process and if the intelligent building is overdesigned just to fulfil the intelligent building evaluation index, or there are too many types of equipment, or the equipment are always updated and replaced, the initial concept of intelligent building evaluation index may be broken.

Except the physical index which can be referred to the data, some of the index related to the feeling of users may not be quantified. With the big data, we may tell the trend and changes of the intelligent system. Analyzing the correlation of different data, we may develop an operating mode which works for the Central Taiwan Innovation and Research Park. Thus, the objectives of this research are as followed:

1. **Apply big data in the field of architecture**
   With the integration of data mining tools, big data analysis method and automation system, manufacturing intelligence (MI) can be built to explore and analyze enormous data and information related to the environment of building and the users. MI can be used to explore potential useful information and great forms and concepts for the basis of building management and optimizing resource distribution.

2. **Build an optimized operating mode of intelligent building**
   With the collection of records and data of past experiences, including power consumption, air condition consumption, indoor environment quality, power management system, facilities management system, electrical light current system such big data, data mining can be conducted according to the different degree of intelligence. The correlation and anticipation of the systems and elements of intelligent building will then be analyzed. The analysis will include a matching of the records of power consumption of intelligent building, correction of the related parameters of the building's optimization and test of model in order to build an optimized anticipated model of intelligent building.

2. Literature Reviews

The biggest global issue in this century is how to face the climate changes and reduce carbon emission. In order to reduce the emission, architecture department now becomes the newer approach with bigger potential then industry department. The data reported by the US Department of Energy in the US shows that buildings consume about 41% of primary energy, more than transportation sector and industry sector. (U.S. Department of energy, March 2012)

Not only the energy wastes during the building construction, the progress of facility operating and maintaining but also consume a lot of resources. Especially the consumed resource during facility operating process accounts for up to 80-90% of the entire building life cycle consumption.(Luisa F. Cabeza, 2014)

With the advances in ICT, stronger systems of the communication network of buildings, and enhanced automation of facilities, buildings are being developed from individual control to intelligent buildings with centralized and automatic control. IB integrates DT and buildings, which enhances the operating efficiency of building and the living quality of residents. The intelligence of buildings is developed by technology which includes two main categories: "environment" and "human". Regarding "environment", sensor technology and automatic facilities are utilized to enhance the efficiency of sustainable energy conservation, disaster prevention, and facilities management. Regarding "human", technology is applied to offer intelligent services which make the living safer, healthier, more convenient and comfortable.(Architecture and Building Research Institute, 2011)

The old research methods predicting energy consumption include the ways as follow. (1) vector regression analysis(Bing Dong, 2005) (2) hybrid neural network model(M.R. Amin-Naseri 2008) (3)Decision Tree(DT)(Ahmed et al., 2011) In recent years, with the rapid changes of the structure and pattern of technology, the world has gone through the Era of IT (Information Technology) and the Era of ICT (Information and Communications Technology). It is now getting to the Era of DT (Data Technology). During the Era of IT, machine automation were developed which the machines were manipulated by signals. During the Era of ICT, the transmission paths of signals were changed that people could integrate data, audio and video through different communication methods to make the manipulation more convenient. In the future Era of DT, there will be smart machines which operate in a human's logic without manual manipulation.(Liao et al., 2012)

Data Mining Technology is an artificial intelligence application, rapid gathering valuable information from several kinds of data, for instance, massively parallel processing (MPP) database, distributed database, cloud computing platform, Internet and expandable storage system. Fu Xiao et al. proposed a five-step framework for Data Mining, including data preparation, collection analysis, valuable data mining and clue finding. The data was converting to proper format during the data preparation, enabling to improve the collection quality when it comes to implementation. Moreover, it can also help us to find the hidden value in the huge amount of data by using association rules.(Xiao and Fan, 2014)

3. Methodology

Overviewing the previous researches, the demonstration and discourse on intelligent buildings are quite fragmented, some of them only focus on the environment but ignore the issues on power consumption while some of them focus on energy saving but ignore the comfortability of health of users. However, there are various factors related to the operation of intelligent building. If there is only one factor focused, the evaluation may fail to reflect the real situation. To understand the impacts of differential factors, various measurements should be applied and big data should be analyzed to develop an optimized model for Central Taiwan Industrial Innovation and Research Park. Its efficient operation should also be ensured in order to achieve the least power consumption, highest comfortability and environmental efficiency. The research methods are as followed.

1. **Literature review and comprehensive analysis.**
   Case studies on intelligent building in Taiwan will be conducted. There was a revision of the Intelligent Building Evaluation Index in 2011. The indicators were added to eight from seven and the buildings would be awarded with the labels of diamond, gold, silver, bronze and pass. Thus, this research will focus on the buildings which meet the new version of index and divide them into different categories. Later on, there will be an analysis on different buildings according to their level of intelligence.

2. **Application of Data Mining on the statistics and analyses of operation information.**
   It is very important to analyze the temperature, humidity, illuminance and power consumption of every part of the building and the micro-climate of the exterior part at the phase of data collection. Data Mining is one of the most important methods when applying big data. It is used to reveal the hidden information. Statistical analysis and models building are applied in Data Mining to look for the patterns and relationships of the data.

3. **Simulating the operating mode of Central Taiwan Industrial Innovation Research Park through data analyses.**
   After analyzing, the most applicable temperature, humidity, illuminance and controllable factors will be obtained and they should be applied to the actual operation of the system. An analysis on the power consumption and other external factors should then be carried out. We will revise the related parameters of the optimized model and set up a testing model in order to develop an anticipated model of optimized intelligent building of Central Taiwan Industrial Innovation Research Park.

4. Discussion

There are 78 rooms and 104 public spaces in the IIC located in central Taiwan. In this discussion, first we analyze electrical power utilisation. There are four types such as, Heating, Ventilation and Air Conditioning (HAVC), electricity supply for power, for lighting and for socket. From the monthly power consumption record *(Fig.1)*, July is the highest month for power consumption. Due to the high temperature, the high electricity use is also observed. Interestingly, the power consumption is less before December of 2014. The possible reason is that the part of equipment was not installed yet or the staffs were not fully entered.

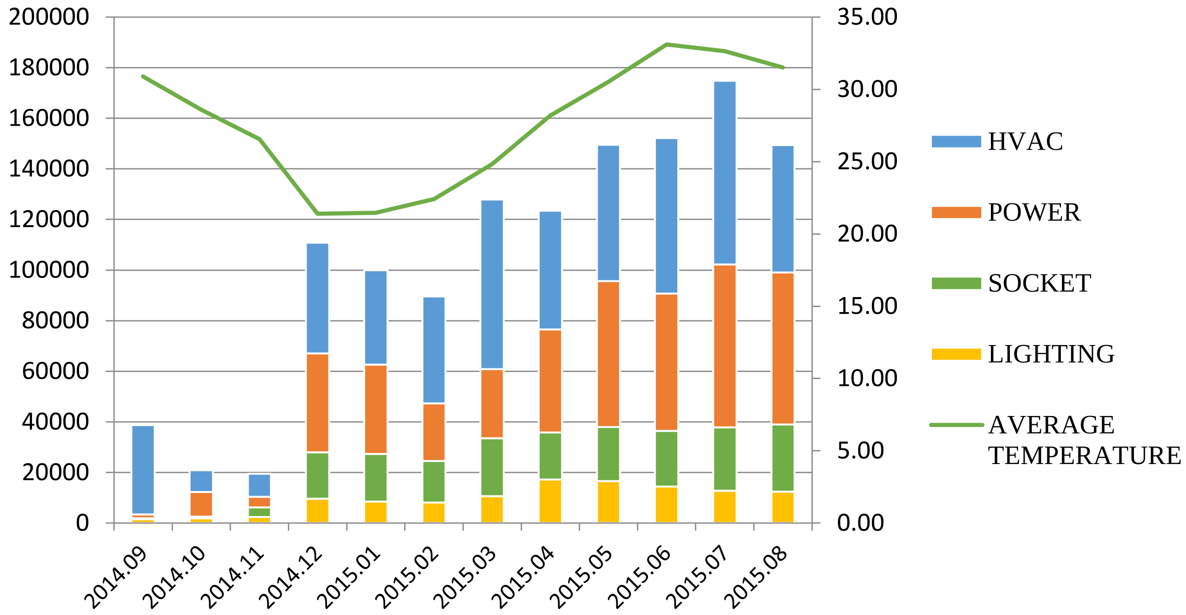

Figure 1: Types of power consumption and average temperature

The bar chart *(Fig.2)* shows the monthly power consumption proportion for 78 indoor zones. For example, the power consumption in September and October in the office of Greenhouse system Technology Center (Room A110) accounts for over half of the annual consumption. On the other hand, in most of the rooms, the main electricity consumption happened from June to August.

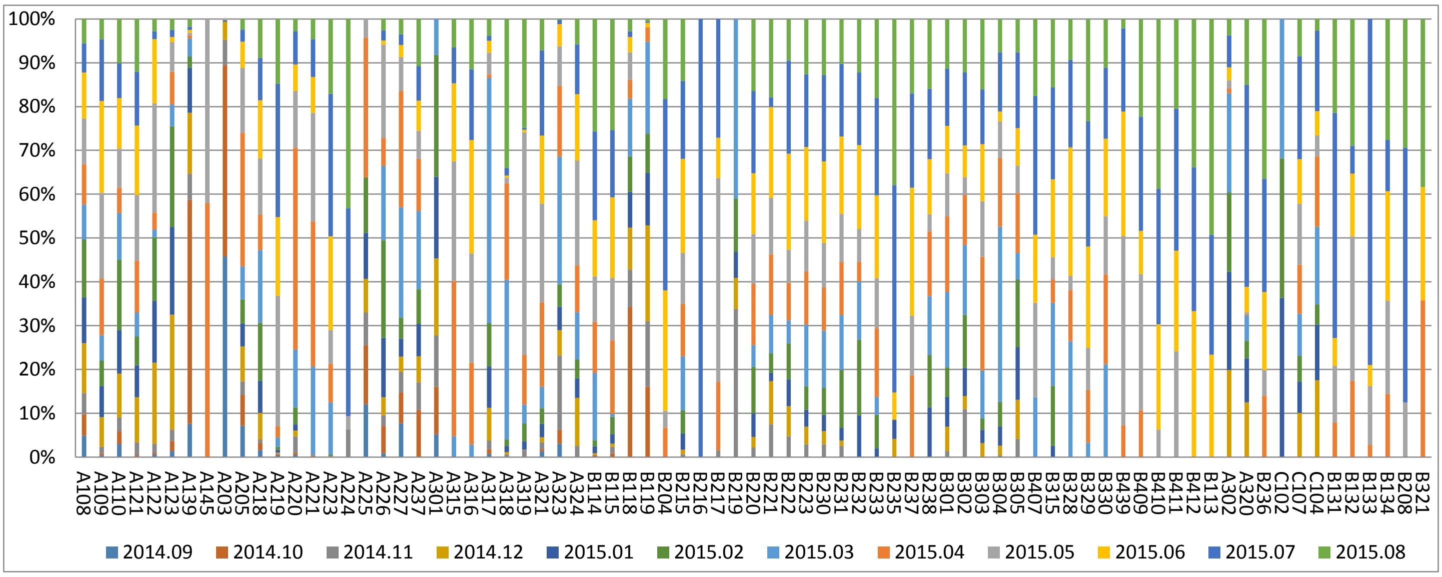

Figure 2: Monthly power consumption of different areas.

The annual electrical power consumption is shown in *Fig. 3* and the power consumption of HVAC accounts for 45% which is nearly half of the annual consumption. Taiwan is located in a subtropical zone and the climate is hot with high humidity. The IIC is located in central Taiwan where the annual average temperature is around 23℃. The average month temperatures from

June to August are higher than other months, sometimes up to 30℃, therefore, the need of the HVAC (air conditioning) is extraordinary increased.

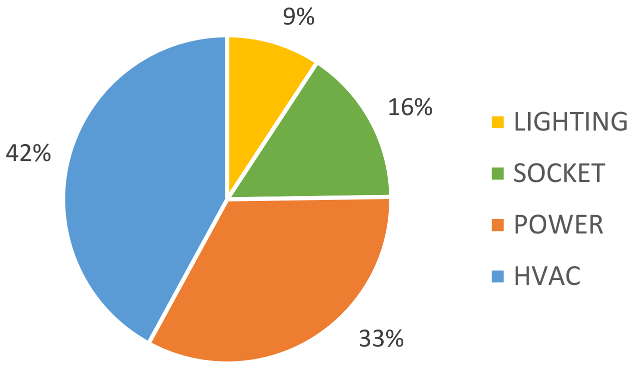

Figure 3: The proportion of annual electrical power consumption

The power consumption of Rapid Prototyping Center (Room A121) in the highest of the whole building and it accounts for almost 10% of the building's annual consumption. The accumulated power consumption of air condition of Room A121 is the highest among the rooms in the building. The power consumption of air condition of Room A219 met the highest in May and July. As the temperature of June and August was higher than the temperature of May and July but the power consumption of air condition of June and August on half of that of May and July, the factor of temperature may be excluded. The power consumption of air condition of Room A223 met the highest in July and it may be due to a more frequent use of that space.

The office of Greenhouse Technology Center on the first floor (Room A110) consumed nearly double of the average monthly air condition power in February. The office of Greenhouse Technology Center on the second floor (Room A205) consumed nearly five times of the average monthly air condition power in April and it may because the office was more frequently occupied that month.

Table 1: Room number and name

Room Number	*Name*
A110	the office of Greenhouse System Technology Center *on the first floor*
A121	Rapid Prototyping Center
A219	Computer Aided Design Greenhouse Laboratory
A223	Automatic Cultivation System Laboratory
A205	the office of Greenhouse System Technology Center *on the second floor*

The top 15 rooms are responsible for 50% of the annual electricity consumption in whole building. There are five rooms, A121, A219, A223, A110 and A205 which the main electricity consumption of these rooms are all from HVAC. The four main factors of HVAC system are Building type, Equipment distribution, Outdoor environment and User behavior. In this study, the Building type and Equipment distribution are set as fixed factor, then the relationships between outdoor temperature and power consumption will be observed. After that, by changing the behavior of the users, the electric consumption of the IIC will be adjusted.

By using Data Mining, the frequency of the staffs enter or exit the rooms from June to August and the relevance between the HVAC electrical consumption and usage by staffs can be analyzed and investigated. Fig. 4 shows the occupancy in different period in those five rooms, excluding the access of the security guards and cleaning staff. From the Fig.4, the period without staff passing can be estimated by Replace Missing Value Interpolation Line. Next, by using Data Mining and we found out the unoccupied period are mostly in afternoon.

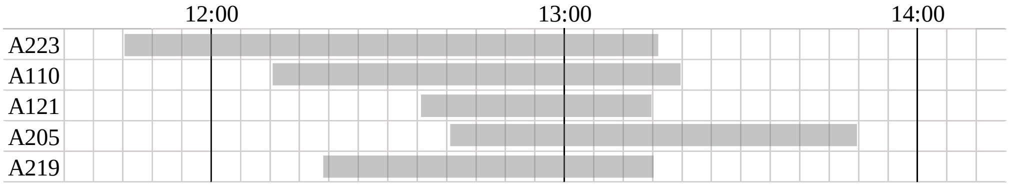

Figure 4: the period without staff passing

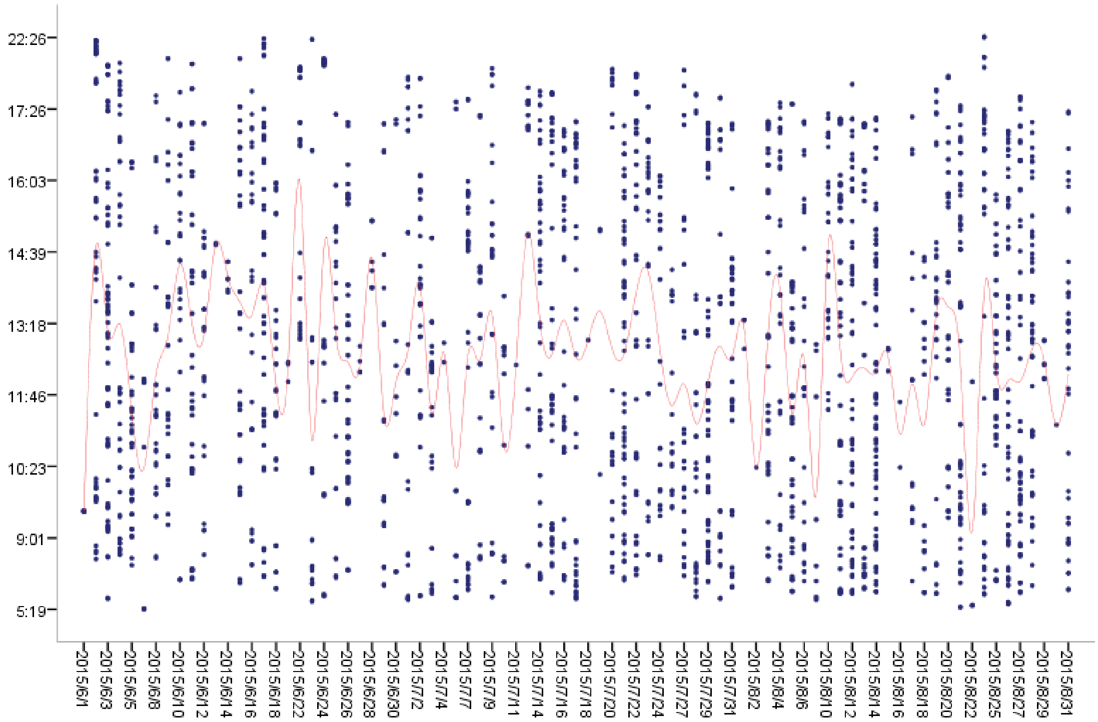

Figure 5: the frequency of the staffs enter or exit the rooms from June to August in A223

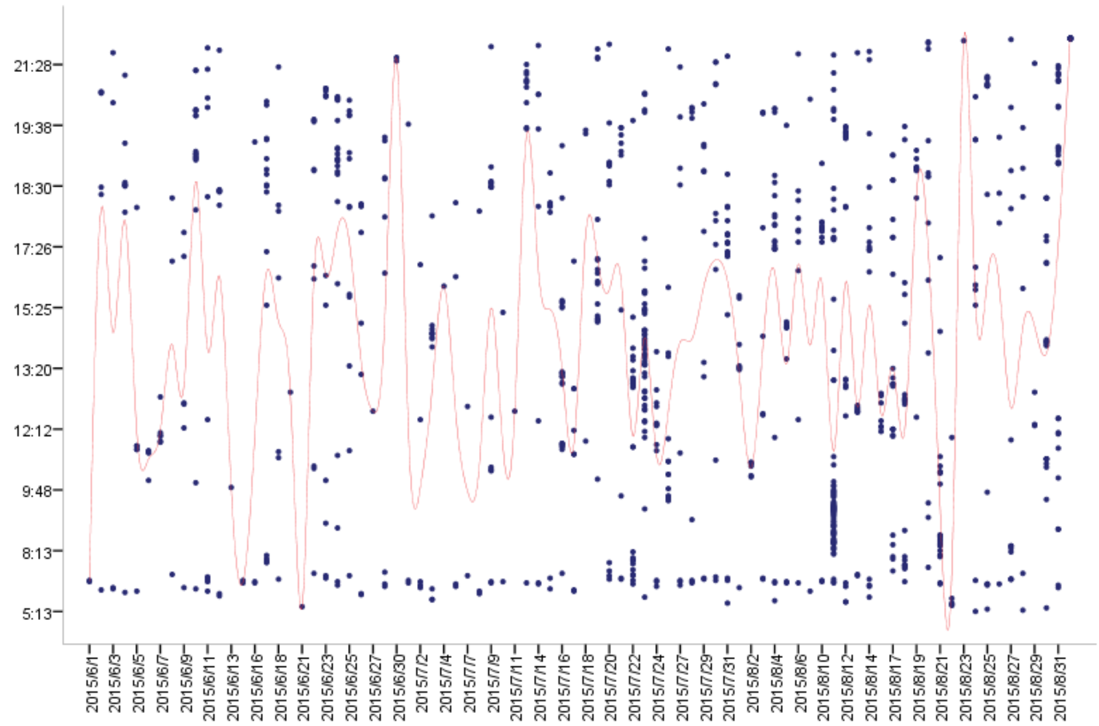

Figure 6: the frequency of the staffs enter or exit the rooms from June to August in A110

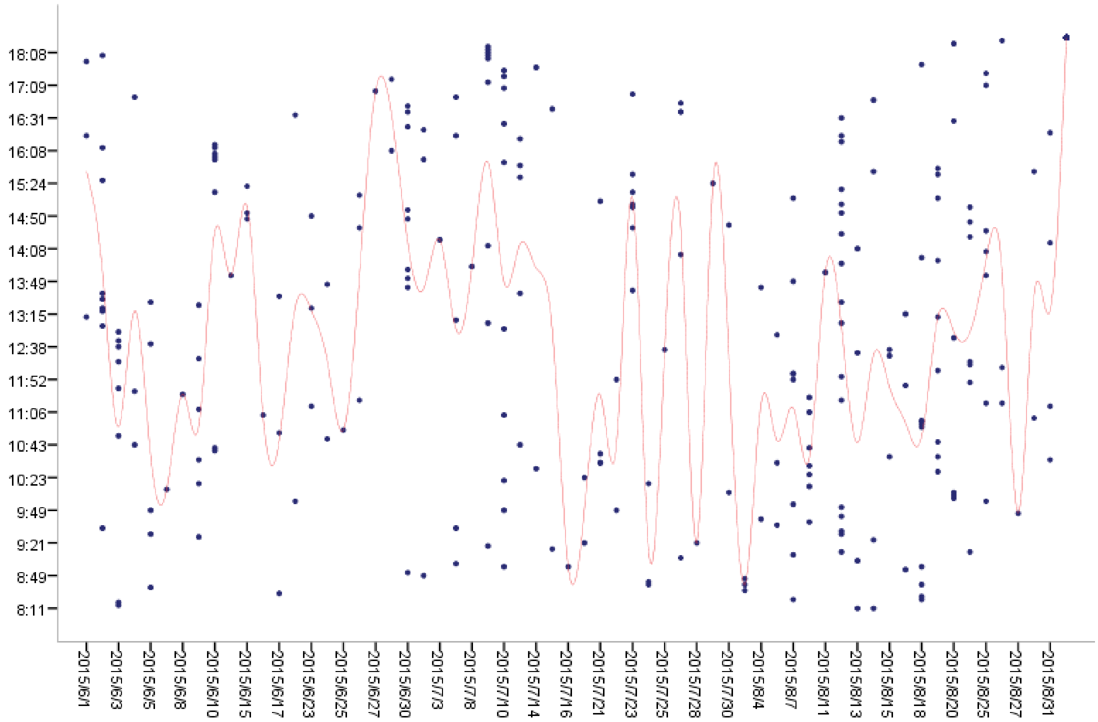

Figure 7: the frequency of the staffs enter or exit the rooms from June to August in A121

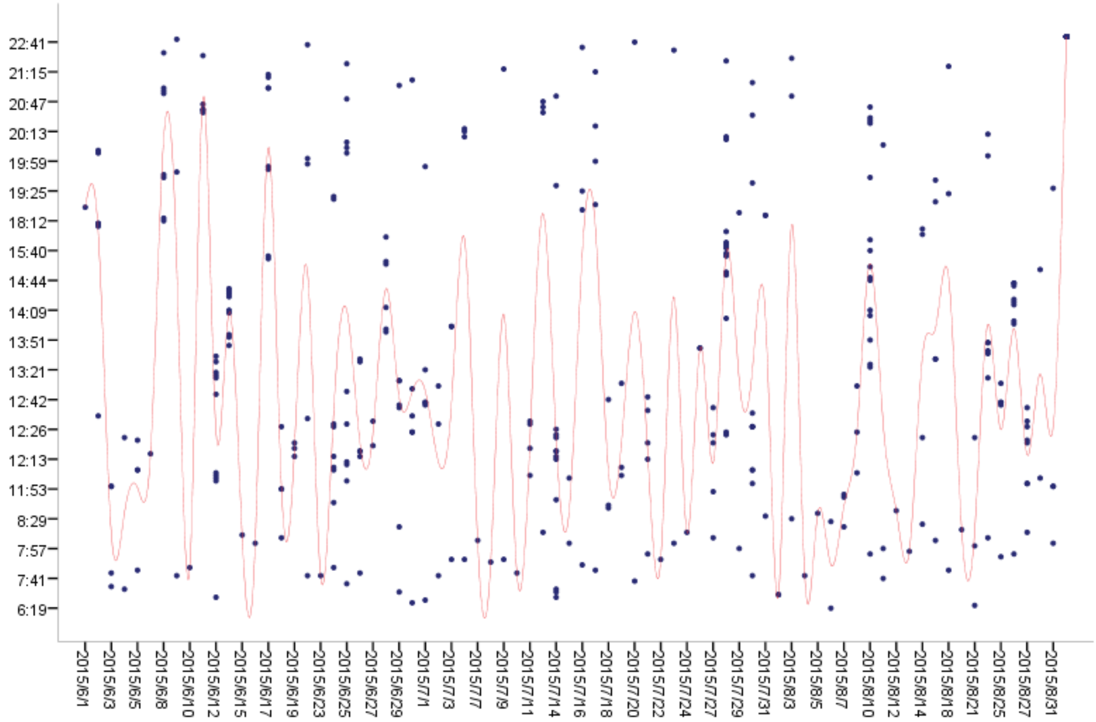

Figure 8: the frequency of the staffs enter or exit the rooms from June to August in A205

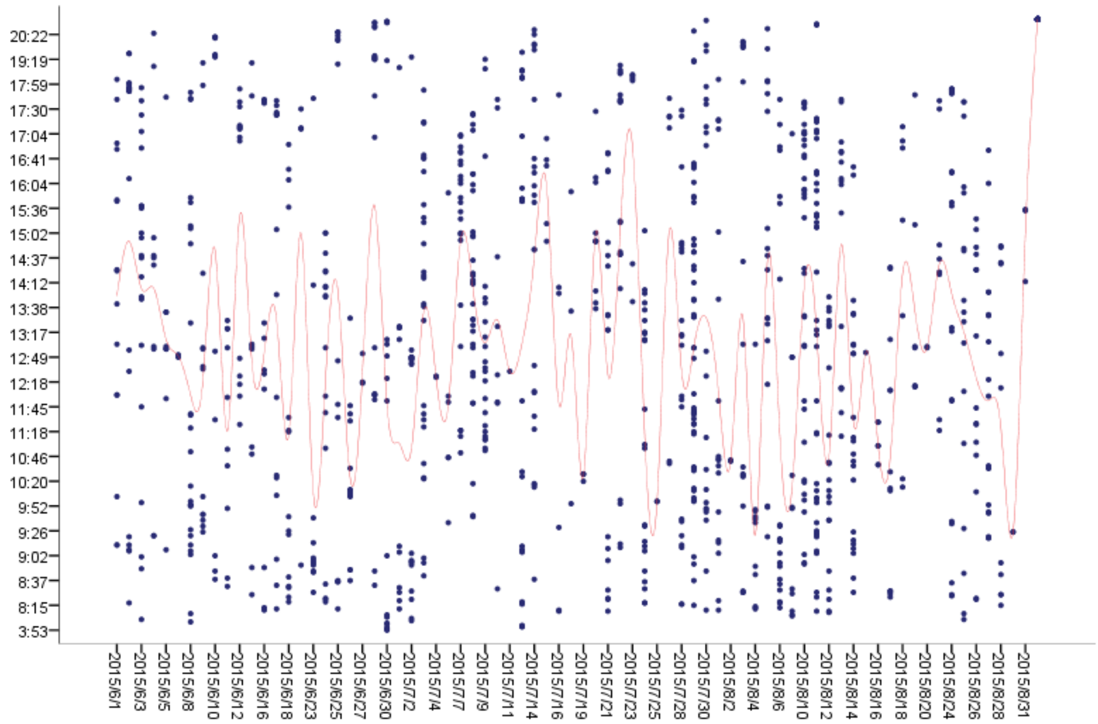

Figure 9: the frequency of the staffs enter or exit the rooms from June to August in A219

5. Conclusions

From the analysis above, the HVAC electric consumption has no absolute correlation with temperature, the number of users are also possibly involved. In this analysis of the five rooms, the time was set as variable factor. If the HVAC system was set electricity-off during 12:45-13:15, it is expected in simulation data that nearly 6% of electric consumption can be saved during the period from June to August. In other public space, since the lowest temperature that the air conditioner can adjust to is limited, if we set the temperature to 1 or 2 Celsius degrees higher, the air condition will consume less power and it will not be over-run. In addition to some of the spaces mainly use power current and the power current consumption may not be forced to reduce after an optimized operating mode is set up since the consumption is related to the period and frequency of use. However, if the power consumption can be changed due to the temperature or other controllable factors, we may adjust the standard temperature or physically change the temperature so as to reduce the power consumption of air condition.

The charts above show only the analysis of five rooms which are responsible for 50% of entire building electric consumption and only the prediction of the three months with highest temperature of all the rooms in IIC. In the following research, we expect to use the data of all areas in analysis and also take the combination of the using frequency, temperature and other quantifiable factors into consideration.The IIC has been operating one year and half only, there will be more data to be collected and analyzed afterwards. By using the data, the operation will be predicted and run for test. With the analysis of Big Data, the more accurate and smarter ways of operation can be provided, in order to optimize the operation mode.

Abstract

To promote carbon-reduction of buildings, increase living qualities and guide the innovative development of the industry, Taiwan has authorized the promotion program of Intelligent Green Buildings in 2010, and the program will be co-organized and led by the government departments in collaboration. However, are these intelligent buildings operating "intelligently" according to the Taiwan Intelligent Building Evaluation System and actual implementation situations? Although Taiwan has self-developed automatic sensor and communication technologies for a long time, the "response" feature of the sensor technology in the building facilities and systems are inadequate for the automatic operation and maintenance of the intelligent systems. This is a hidden issue within the intelligence system development that needs to be answered. Hence, this study will focus on the automation of operation and maintenance of environmental factors detected in ICT and the disaster prevention, electrical supply, water supply, wastewater, air-conditioning, communications and transport systems. For example, when indoor carbon dioxide concentration exceeds 1000ppm, the air- conditioning system should open a shaft to allow fresh air to enter; when indoor air quality returns to preset conditions, the system will automatically shut down the ventilation system. This study shall use Taiwan case studies that have achieved the highest level of Intelligent Building Label as targets and explore the relations and links between the different connected systems and the controlling logics. In other words, it will mean using an integrated series of logic controllers to determine system responses, allowing the building to function with consciousness and create human-centered living spaces according to different requirements or basic environmental factors, so that the building may become a truly intelligent building entity.

Keywords: Intelligent Building, Logic System, Integration

1. Introduction

With the advance of modern technology and demand of people, the automated systems of different kinds of building have been constantly innovated and developed. There are various and complex innovations and development, for instance, air condition, electrical power and illumination system. However, the applying service subsystems from different manufacturers usually have different coding format which cause the differences of communication rate, coding format, ways of synchronize and communications specification. As a result, resource cannot be shared between the system facilities and the messages cannot be transmitted and coordinated which limit the efficiency of services management and the development of sustainable operation management. Therefore, this research focuses on the environment factors detected by the monitoring system and also the facilities such as disaster prevention system, electrical system, water supply and drainage system, air condition system and communication of the intelligent building system. It focuses on the automation of operation and maintenance management as well. In short, this research has applied a series of logical integration to give the building the features to serve as a more occupant- friendly and favourable living space according to different demand or environmental condition to become a real intelligent building.

In this research, we have reviewed the Industrial Innovation Center in Taiwan's experience on applying for the Intelligent Building Label. We have found that there are some problems of the operation of intelligent buildings needed to be discussed; especially the links and the interaction between each intelligent system which fail to achieve the original goals. Since they are still manual-controlled, they are not intelligent but automated. The significance of intelligent buildings is lost when the designed intelligence does not work well. For example, when the air quality detector senses poor indoor air quality, it draws fresh air into the indoor proactively to reduce the indoor concentration of CO_2. However, if the temperature is high outside, the drawn air will also raise the indoor temperature which increases the need of air condition. This example only presents the failed coordination between two facilities and we can imagine how complicated it is when an intelligent building connects a number of facilities at the same time. Hence, to achieve "intelligence", we must find the key points and directions of system integration, as well as focus on the strategies of software system integration and planning and the feasibility studies. The system integration and logic establishment of the coordination between the software and hardware in intelligent buildings should be analyzed. The objectives of this study are as followed:

1. System integration and logic establishment
Through case studies, we have analyzed the links between each system, as well as the main factors affecting the logic establishment and other correlation coefficients. We hope to enhance the intelligence of buildings which serve as a human-oriented and favourable living space based on different demands and environmental conditions.

2. Enhancement of efficiency of intelligent buildings
When the management efficiency and the ability in system integration of intelligent buildings are enhanced, the operation cost of buildings can also be reduced. With the automated devices and systems, the limited resources and the spaces may be utilized and developed to offer a comfortable, safe and convenient environment, as well as to save the buildings' expenses and resources consumption.

2. Literature Reviews

This research focuses on the integration of logic systems in intelligent building system; therefore, The literature review and theoretical framework include the following topics:
(1.) The definition of intelligent buildings and the importance of system integration
(2.) The application of intelligent systems
(3.) The definition of logic and the logic that this research adopts

2.1 The definition of Intelligent Buildings

In short, intelligent building refers to the integration of information and communication technology (ICT) into a building in order to enhance the efficiency of the building's management and the living quality of occupants. Regarding "human", internet technology is applied to offer intelligent services such as assistive functions of safety, health, convenience and comfort. Regarding "environment", sensor technology and automated facilities are applied to raise the sustainability and energy efficiency, safety and disaster prevention, and facilities management efficiency of buildings(Architecture and Building Research Institute, Ministry of the Interior, 2012).

Professor Clements-Croome from University of Reading defined that intelligent buildings are not completely buildings of high-technology but are able to change in accordance with the needs of occupants. They have to be highly-sustainable and provide the occupants the space to interact so as to enhance the living efficiency(Derek,2013). Thus, we believe that we should pay high attention when we analyze how to enhance the buildings from the "automated" stage to "intelligent" stage based on the progress of modern technology, as well as the architectural development in this generation.

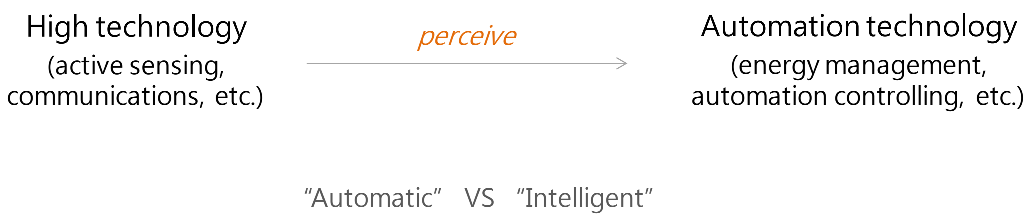

Figure 1 Relation between "automatic" and "intelligent"

The integration of a building's facilities with other related intelligent construction technology is emphasized in the functions of intelligent buildings. The integration includes automated building systems and technologies, occupied space, operating and management mechanism and how to introduce high-performance control functions to achieve the safety of air condition, illumination and disasters prevention such facilities, energy conservation and environment protection while maintaining good indoor environment(Wen,1999).

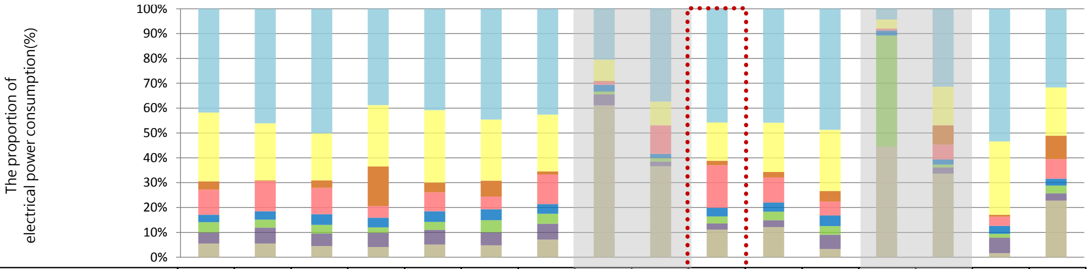
Currently, when it comes to the formation of intelligent space, the most discussed issues are (1) device heterogeneity, (2) device awareness, (3) come and use, (4) limited resource, (5) integrated multiple service management, (6) home service sharing, (7) security, (8) quality of service (QoS), (9) pay per use, (10) user authentication and (11) preference. It is to be hoped that through the integration of human, the internet and facilities, the intelligence of facilities can be enhanced and introduce the central concept of "human oriented", as well as include the related topics of health, comfort and safety(Shaikh, P. H, 2014)(Architecture and Building Research Institute, Ministry of the Interior, 2012).

Moreover, as we have come to a new generation, there have been more technological and automated services introduced in accordance with the occupants' demand. Nonetheless, the types of system are varied and always increasing. For intelligent buildings, what is saved from resource sharing, and the maintenance, change and expansion in the future of these different facility systems, or the coordination between systems and enhancement of manipulation management will affect the sustainable development of buildings. Consequently, it is necessary to consider the system integration of building which is expected to increase the efficiency of management and integrated services, reduce the dependence on labor force as well as the operating and management cost of buildings in the future.

2.2 The definition of Logic

The definition of the term "logic" includes (1) the principle of objective things, (2) a theory or a view point, (3) the rule of thinking and (4) the science of reasoning.

According to the annual report of Bureau of Energy, Ministry of Economic Affairs, in addition to special types of buildings (for example, tracks in a railway station, telecommunication equipment rooms, wastewater treatment plants and warehouses), the air condition system and illumination system account for the most electrical power consumption of different sorts of buildings. In average, the air condition system and the illumination system account for approximately 32% to 54% and 15% to 30% of the total electrical power consumption respectively. In another word, they account for 60% to 70% of the total consumption of the buildings(Taiwan Bureau of Energy, Minist of Economic Affairs,2013). (See Figure 2)



System \ Type	School	Office Building	Hospital	Hyper-market	Department Store	Hostel	Government Agencies	Railway station and tracks	Telecommunication Equipment rooms	Research Building	Exhibition Center	Composite Mall	Wastewater treatment plants	Warehouses	Airport	Othres
Air condition system	41.9%	46.1%	50.1%	39.0%	40.8%	44.6%	42.6%	20.5%	37.5%	45.8%	46.0%	48.8%	4.3%	31.3%	53.5%	31.7%
Illumination system	27.7%	23.0%	19.0%	24.7%	29.2%	24.6%	22.9%	8.6%	9.5%	15.4%	19.8%	24.7%	3.7%	15.5%	29.5%	19.4%
Refrigerate and freeze system	3.3%	0.3%	3.0%	15.9%	3.9%	6.4%	1.2%	0.2%	0.1%	1.8%	2.2%	4.2%	0.1%	7.8%	0.8%	9.4%
Sockets system	10.1%	12.1%	10.6%	4.7%	7.6%	5.1%	11.9%	1.3%	11.4%	17.1%	10.1%	5.6%	0.7%	6.0%	3.7%	7.9%
Air supply and exhaust system	3.0%	3.4%	4.3%	3.9%	4.3%	4.4%	3.9%	2.7%	1.7%	3.5%	3.7%	4.3%	2.0%	2.0%	3.2%	2.8%
Water supply and drainage system	4.2%	3.2%	3.5%	2.2%	3.2%	4.9%	4.0%	1.2%	1.4%	2.8%	3.4%	3.5%	44.7%	1.2%	1.5%	3.1%
Elevator system	4.4%	6.4%	5.0%	5.7%	5.9%	5.2%	6.4%	4.4%	1.9%	2.5%	2.8%	5.7%	0.0%	2.5%	6.3%	2.9%
Other systems	5.5%	5.5%	4.5%	4.1%	5.1%	4.8%	7.1%	61.1%	36.6%	11.1%	12.1%	3.3%	44.5%	33.6%	1.6%	22.8%

Figure 2 Distribution of electrical power consumption of different buildings(Source: Energy saving of building Manual, Bureau of Energy, Ministry of Economic Affairs)

Hence, a conclusion of the above statement is conducted when discussing logic in this research. The proportion of electrical power consumption is the basis of logic control; for instance, the proportion of electrical power consumption of air condition system, sockets and illumination are respectively 45.8%, 17.1% and 15.4% in a research building (Figure 3), According to a foreign study on energy saving potential, the system for distinguishing energy consumption is also divided into four categories (Nguyen, 2013). After categorizing the buildings, we have mainly discussed these four types of consumption. In brief, we have first controlled the equipment which consumes the most electrical power, following other equipment.

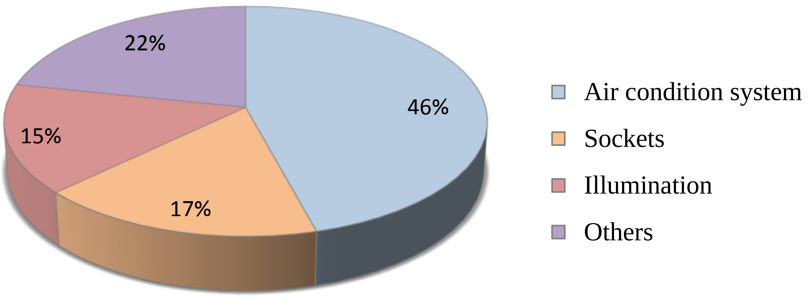


Figure 3 Proportion of electrical power consumption of research building.

However, in order to achieve improvements in building energy use at this stage, logic discussions of individual systems are necessary based on the illumination of public buildings and the air condition system(C. Aghemo et al., 2013); studies discussing the adoption of a classification method are also required to draw up an air condition system control logic (G.Graditi et al., 2015), etc. in a reasonable usage method with the living space as an example; however, the single system is generally adopted as the study case.

3. Methodology

3.1 Literature Review and Theoretical Framework

With various technologies, designs, and equipment related to intelligent buildings, in order to gather information about intelligent building applications and the current situation of development, we will collect both domestic and foreign design data related to intelligent buildings, as well as relevant literature regarding energy saving technology, equipment, design concepts, etc., in order to make a review to better understand the latest application condition of this technology and provide a reference and application for subsequent studies and discussion.

3.2 Correlation Analysis

This study adopts data collection and research as analysis research methods. Therefore, it first categorizes each system as 「Air conditioning, Illumination, Sockets, Power Current」 through the intelligent buildings, then performs a preliminary screening of the space, and finally discusses the relationship between the average total electricity consumption of air conditioning, illumination, sockets, power current and the total quantity of the electricity of the above four items together. As mentioned above, in order to observe two or more variables to determine whether other variables can be predicted from another major variable, 「Correlation Analysis」 in the statistics will be adopted as the method of this study: Pearson's Correlation will be adopted to analyze the correlation degree of the two, and the correlation coefficient (γ_{XY}) may serve as the pointer of linear correlation between two continuous variables and is defined below:

$$\gamma_{XY} = \frac{s_{XY}}{s_X s_Y}$$

γ_{XY} = Sample correlation coefficient　　s_X = Sample standard deviation of X

s_{XY} = Sample covariance　　s_Y = Sample standard deviation of Y

(1) The value of the correlation coefficient is constant between -1 and +1.

(2) +1 shows that X and Y belong to the completely positive linear correlation, while -1 shows that they belong to the completely negative linear correlation. If the value of the correlation coefficient is very close to zero, then no linear relation exists between X and Y.

(3) The correlation degree represented by the correlation coefficient is shown in Table 1.

Table 1 Correlation degree represented by the correlation coefficient

Correlation coefficient (r)	Correlation degree
Above 0.8	Extremely high
0.6 - 0.8	High
0.4 - 0.6	Average
0.2 - 0.4	Low
Below 0.2	Extremely low

After calculating the correlation coefficient, its value was found to be increasingly close to 1, indicating that the space is more correlated to the system of this class, thus improving the understanding of the correlation degree of usage amount of these four electricity consumption classes in a space, determining the order of use of each system, and discussing its operation logic.

4. Discussion

We have taken the Industrial Innovation Center in Taiwan as an example. The interior system is categorized into “air condition”, “illumination”, “sockets” and “power current” and the actual electrical power consumption have been discussed.

Table 2 Categories of intelligent system of Industrial Innovation Center in Taiwan

Category	Air Condition	Illumination	Sockets/ Light Current	Power Current	Others
System	Air quality	Illumination control	Door security system	Flood prevention	Division of fire protection
	Air condition system		Emergency system	Ground system	Energy saving and management
	Environment and wind monitoring system		CCTV system	Lightning protection system	
			Automatic pay station for car parking	Emergency generator	
			Environment monitoring system	Water supply and drainage system	
			Leak and flood detection	Environmental control power	
			Facility management system	Environment and water monitoring system	
			Other light current system	Renewable power system	

			Home automation system	Elevator	
			Spatial Assisting		
			Information Service		
			Fire alarm system		

(Data source: Summarized in this study）

Furthermore, as the place of this case lies in a circum-subtropical zone, the summer climate from June to August is the hottest part of the year. Therefore, the total electricity consumption data (as shown in Figure 4) of each space from June to August of 2015 is summarized to discuss the topics that can be researched, analyzed and improved with regard to the relatively extreme values. Of the 205 spaces, 51 had an electricity consumption that exceeded the average value, including seven spaces with an electricity consumption that exceeded the standard deviation of 1. This study classifies the use of each space as follows:

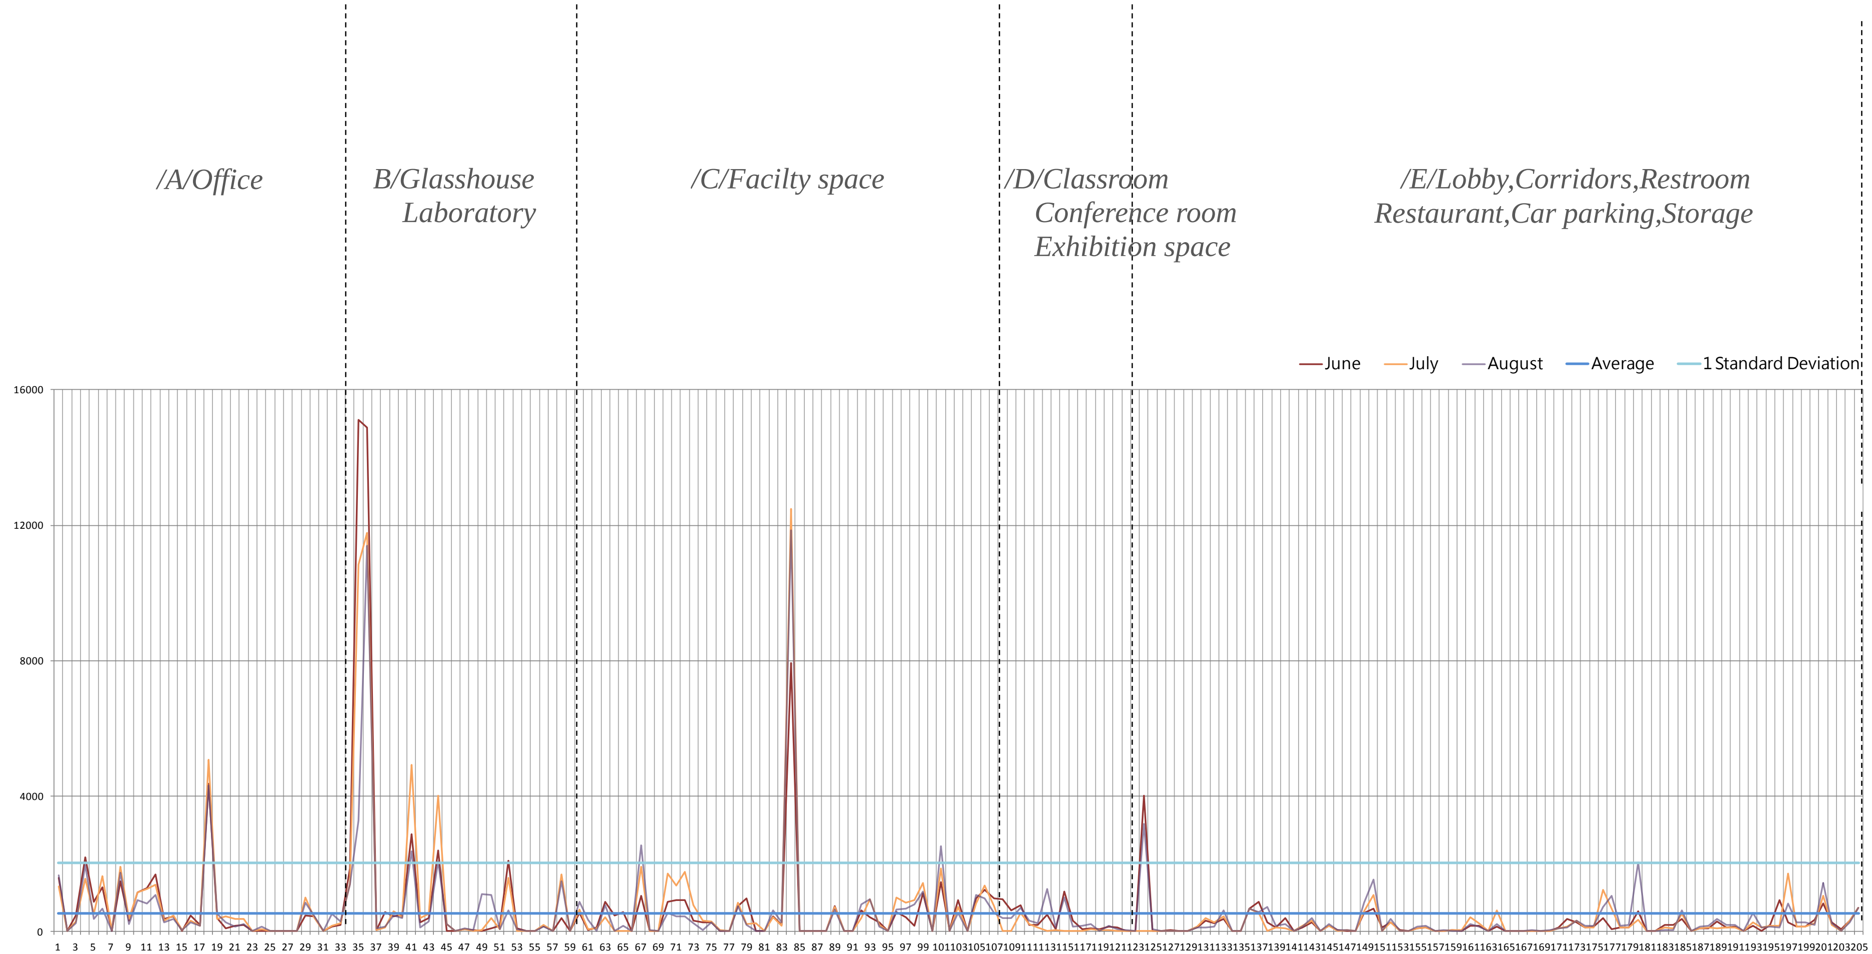

Figure 4 Electrical por consumption of different spaces

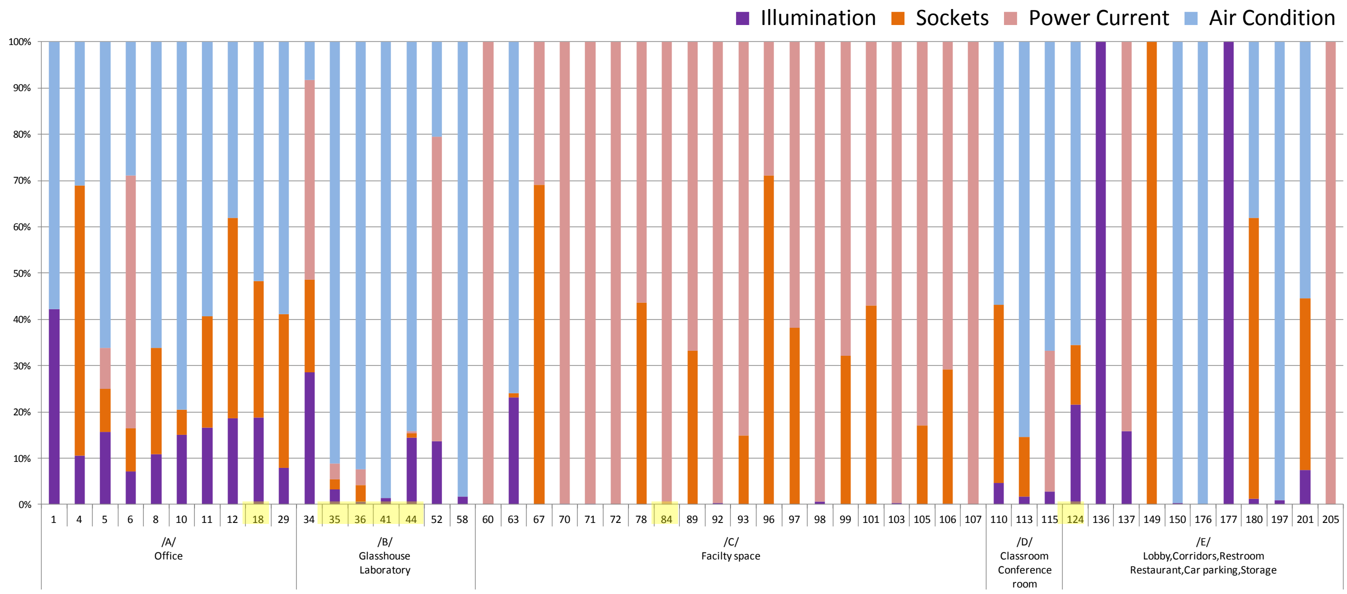

Figure 5 Proportion of electrical power consumption of different spaces in June.

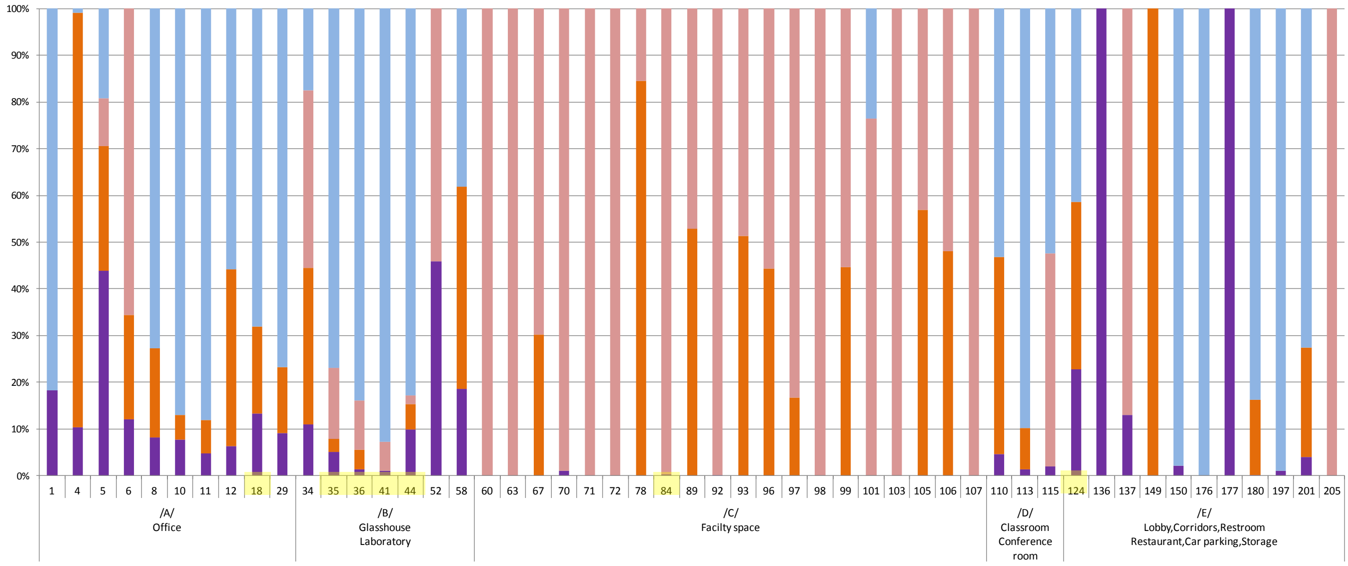

Figure 6 Proportion of electrical power consumption of different spaces in July.

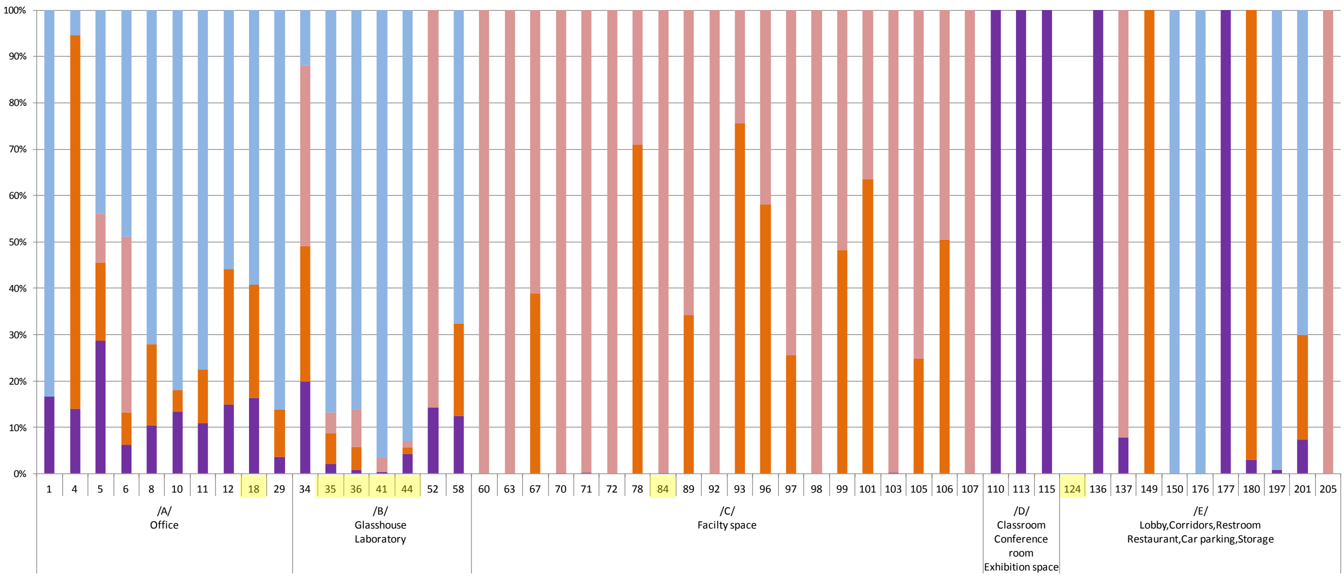

Figure 7 Proportion of electrical power consumption of different spaces in August.

4.1 Different space type analysis findings

Figure 5, Figure 6, and Figure 7 show the 51 spaces whose total electricity consumption exceeded the average value from June to August. Among them, the designation A, B, C, D, and E below indicate the class of space; the number represents the code of each space; and the areas marked with a yellow color block represent the total electricity consumption of this space that exceeds the standard deviation of 1. According to the electricity consumption proportion of each space with different uses, the main energy consumption class and total electricity consumption (as shown in Figure 8) of the space also differ.

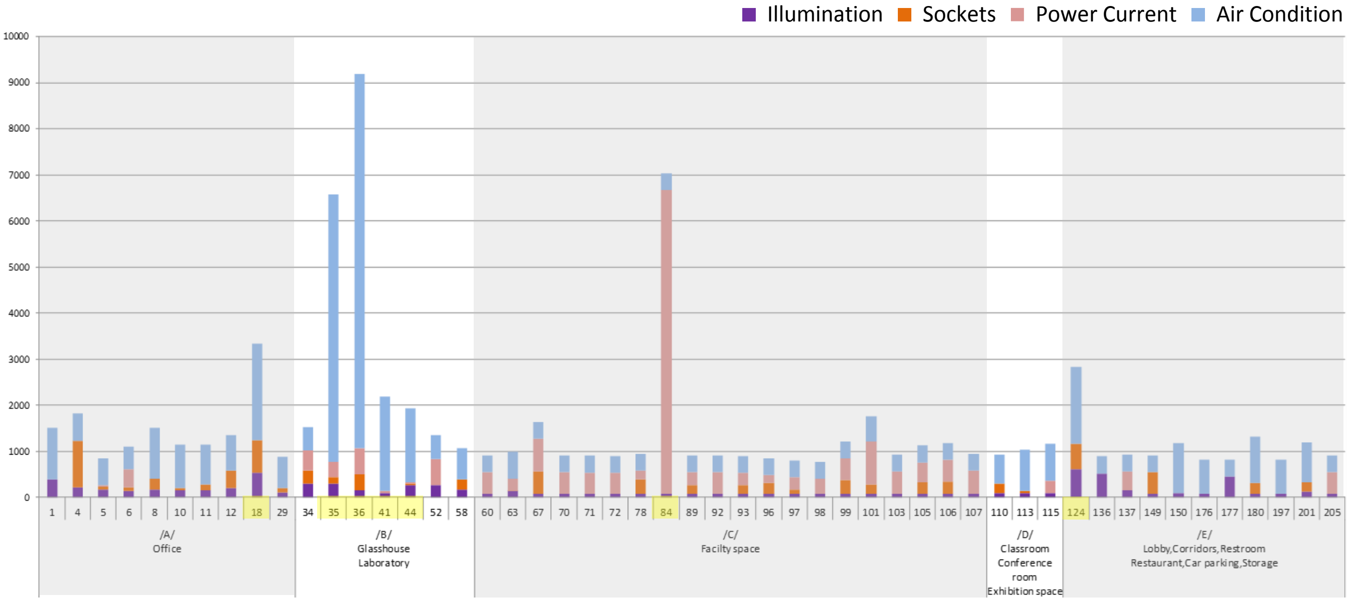

Figure 8Proportion of electrical power consumption between June and August

/A/ Office Space

The consumption of electricity for illumination, sockets, power current, and air conditioner items mostly presents a relatively uniform usage state. The systems' categories calculated using the correlation coefficient are summarized below from highest to lowest; as its value becomes closer to 1, the space is more correlated to the system of this category: **air conditioner (r=0.934), illumination (r=0.845), sockets (r=0.783), and power current (r=0.118).**

Furthermore, we drew a scatter diagram of the correlation degree, as shown in Figure 9. Using air conditioning as an example, the x-axis represents the average electricity consumption of the air conditioning category from June to August, and the y-axis represents the total electricity consumption for illumination, sockets, air conditioning, and power current from June to August. The scattered point is more densely distributed in the simple linear regression trend on-line, indicating that the air conditioning is more correlated to the office class space.

Using the system of Central Industry Innovation Research and Development Zone of Taiwan's Industrial Institute as an example, the system logic deduction used for office space is as follows: **Air conditioning system > Illumination control > Firefighting system.**

Among them, the electricity for sockets is the electricity mainly consumed by office equipment. The electricity for the power current is generally not applied in the system, so there is no arrangement.

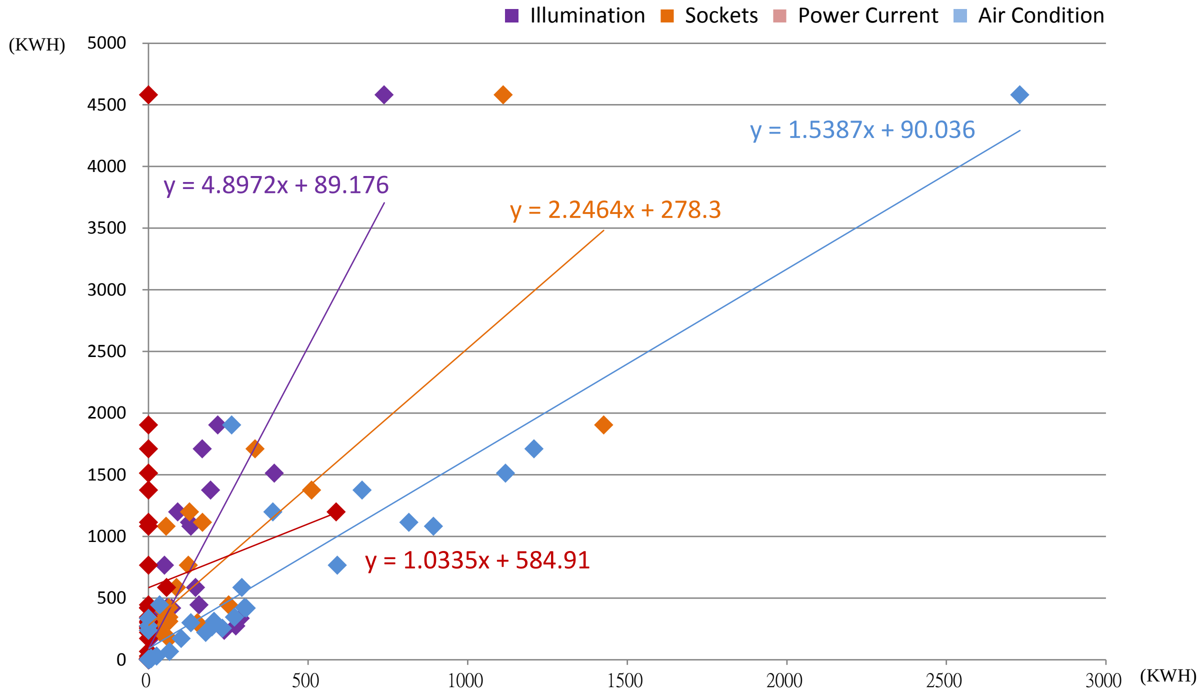

Figure 9 Correlation diagram of each system class in the office space

/B/ Glasshouse and Laboratory

Owing to the fact that the areas are majorly used as glasshouses and precision instruments are used and installed there, there is a more apparent use of air condition comparing to other space types (e.g. Figure 8, code 35, 36, 41, and 44). The correlation coefficient of each class is summarized below: **air conditioner(r=0.992), sockets (r=0.628), power current(r=0.625), illumination (r=0.428).** The system logic deduction is: **Air conditioning system** > **Air quality system** > **Firefighting system** > **Illumination control**

Among them, the electricity used for sockets is mainly the electricity consumed by greenhouse or research equipment, except for the part of electricity consumed for detection of the firefighting system. The electricity used for the power current is also the same; thus, there is no arrangement.

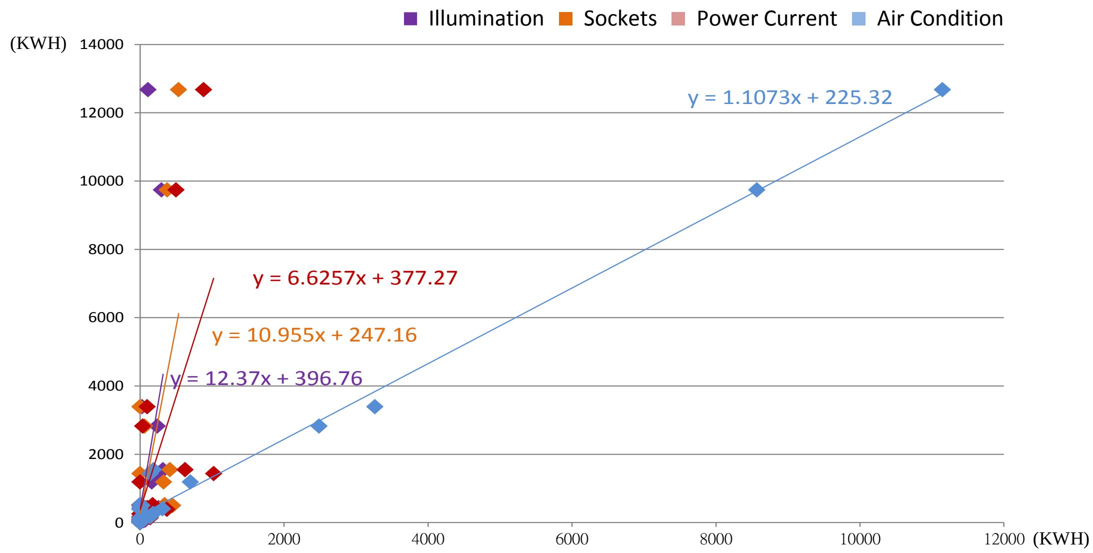

Figure 10 Correlation diagram of each system class in the glasshouse and laboratory space

/C/ Faculty Space

There are many huge machines in this space type which generate heat during operation. Therefore, air condition is necessary to adjust the temperature so as to maintain the operation of machines.The correlation coefficient of each class is summarized below: **power current(r=0.990), sockets(r=0.134), air conditioner(r=0.058), illumination(r=0.029).**The system logic deduction is: **Emergency generator system > Environmental control power system > Firefighting system > Air conditioning system > Illumination control.**

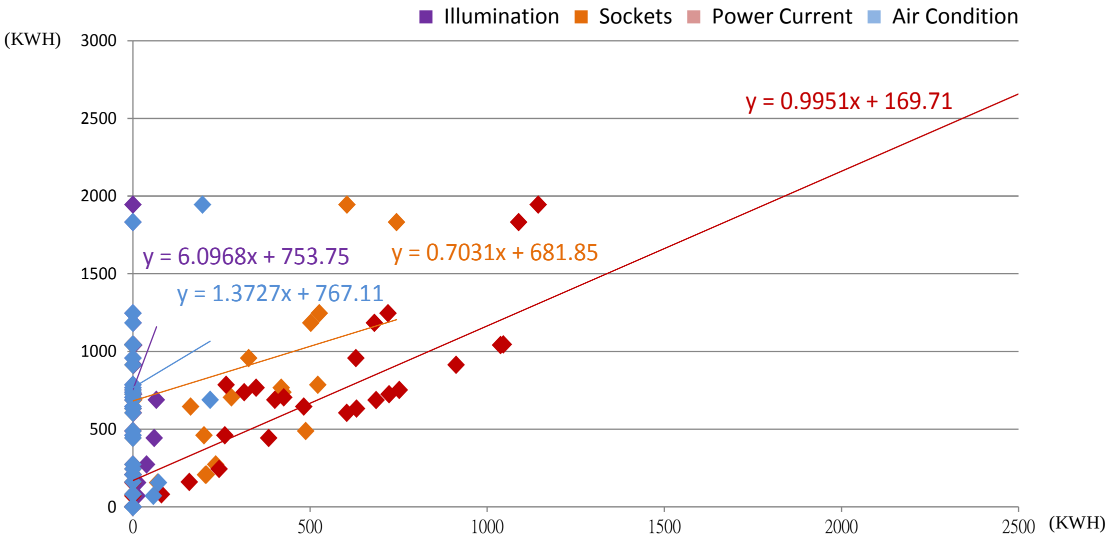

Figure 11 Correlation diagram of each system class in the faculty space

/D/ Classroom, Conference room and Exhibition space

In addition,some of spaces are only occupied sometimes so they only consume power for illumination during normal occasions, such as experience room, meeting room and show area. (Figure5.6.7 /D/ class of space) .The correlation coefficient of each class is summarized below:**air conditioner(r=0.889), illumination(r=0.525), sockets(r=0.505), power current(r=0.067)**. The system logic deduction is: **Air quality system > Air conditioning system > Illumination control > Firefighting system.** The electricity used for sockets is mainly the electricity consumed by the equipment, while part of the space may have electricity consumption with regard to power current under particular usage conditions. Therefore, this correlation is extremely low.

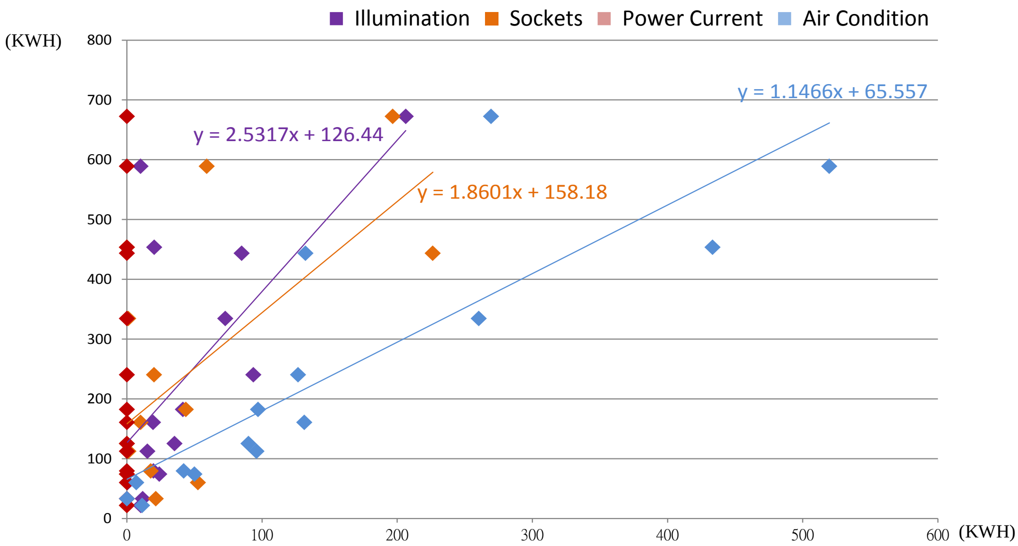

Figure 12 Correlation diagram of each system class in the classroom, conference room and exhibition space

/E/ Lobby, Corridors, Restroom, Restaurant, Car parking and Storage

The major electrical power consumption of this space type is quite different. For example, illumination is the major consumption for the car parking, air condition is the major consumption for the lobby, pantry and elevator lobby, and power current is the major consumption for the kitchen.The correlation coefficient of each class is summarized below: **air conditioner(r=0.851), sockets(r=0.636), illumination (r=0.490), power current(r=0.081)**. The system logic deduction is: **Air conditioning system** > **Air quality system** > **Firefighting system** > **Illumination control**.

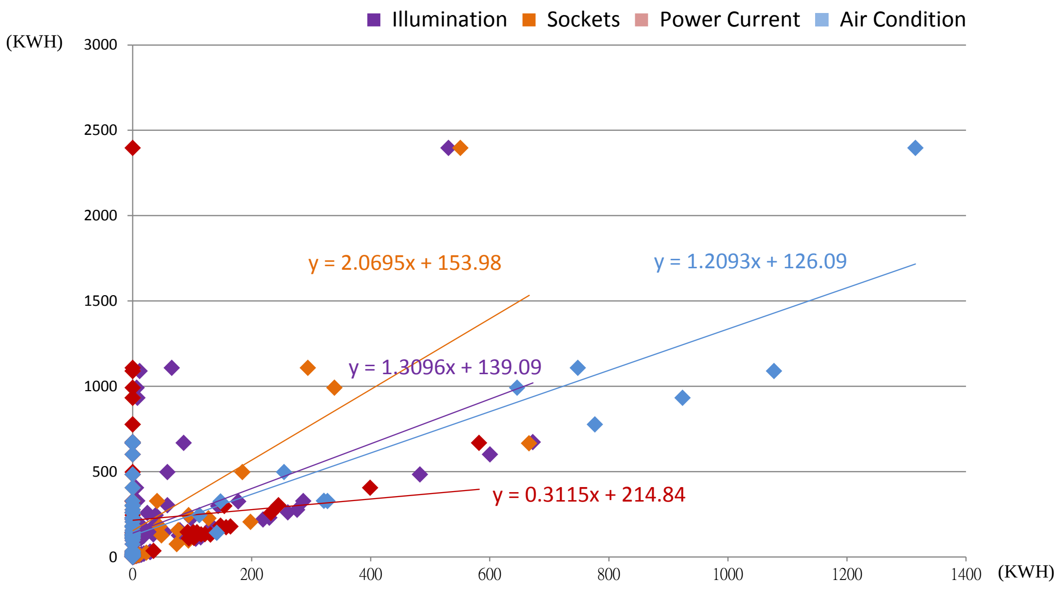

Figure 13 Correlation diagram of each system class in the other space

As we have mentioned, the air condition system and illumination account for the most electrical power consumption of most of the buildings which is approximately 60% to 70% of the total consumption. Nevertheless, our case studies findings show that the air condition system and power current actually account for approximately 70% of the total consumption (see figure 14). From the data shown above, we have inferred that it is because the analyzed building is a research institute which mainly relies on the air condition and power current. Apart from that, it may also be resulted from the good design of adopting the natural lighting of the Industrial Innovation Center which can satisfy the demand of illumination. The illumination only accounts for 11.25% of the total electrical power consumption.

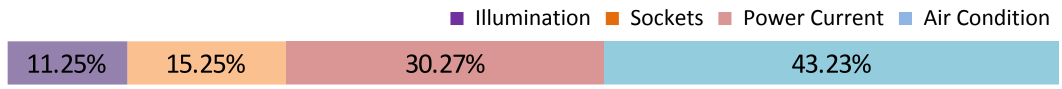

Figure 14 Proportion of electrical power consumption of Industrial Innovation Center between June and August

5. Conclusions

According to the statistics of the annual review report of the Bureau of Energy, Ministry of Economic Affairs in its study of the proportion of electricity consumption in different classes of buildings, it arranged as the following four categories according to the proportion of total electricity occupied: air conditioning, power current, sockets, and illumination electricity. Furthermore, as the above arrangement is only the order of "Total Electricity Consumption" obtained in the case, if the order and control logic of the four system classes are thus deduced, the final conclusions obtained will be unable to completely apply to the space of the ABCDE classes according to their spatial characteristics. Therefore, discussions shall be respectively made according to different "Space Properties".

Furthermore, through the *4.1 Discussion of each space class* section above, the deduced system order of A to E classes is obtained. From the perspective where the logic model of the system applied in this space is deduced, in order to comply with this study's purpose of making energy saving and efficient improvements, different spaces and usage methods can be followed to establish intellectualized regulations and controls according to the logic precedence order, as well as to practically summarize the energy saving countermeasures required for this space in a more friendly way. This research case is illustrated as follows:

(1) /A/ Office space; /B/ Glasshouse and Laboratory; /D/ Classroom, Conference room and Exhibition space; /E/ Lobby, Corridors, Restroom, Restaurant, Car parking and Storage

The system class mainly used for the above spaces mostly takes "Air Conditioning" as the bulk; therefore, this study considers air conditioning energy saving practices and can also further the understanding of the usage situation of spaces (for example, according to the investigation on people's use of some spaces, in the state of non-use for a long time, the system will automatically judge to turn the air conditioning off, regulate the temperature, etc.).

(2) /C/ Faculty Space

The main electricity consumption for the system classes of power current, sockets, air conditioning, and illumination is a small amount. With limited re-improvement efforts with regard to energy saving, in order to maintain the equipment operation in the faculty space, a certain amount of electricity consumption shall be required for the power current. Therefore, this part may determine the mechanical and electronic design during the construction or choose the equipment with better energy saving performance in subsequent updates.

In a future study, the data of other months of each space of the Central Industry Innovation Research and Development Zone will be analyzed, more space information will be adopted to discuss the actual situation in closer relation to this case, and the related data of other construction environments will be collected. Then a detailed discussion will be made on each system of intelligent buildings in order to summarize the establishment and operation of each system of intelligent buildings and inter-system logic models.

Investigating the Maintenance Management Practices for Urban Roads in India

Aishwarya Dudhia and Ganesh Devkar

CEPT University, India
dudhiaaishwarya@gmail.com

Abstract

The demand for quality urban infrastructure has been increasing rapidly in developing countries. In India, there is a huge demand and supply mismatch in the urban infrastructure sector and this situation has been further worsened by the poor maintenance of existing infrastructure. Urban roads in India are reeling under similar scenario and the poor quality of urban roads has been affecting convenience and safety of road users. In this context, the analysis of maintenance management practices followed by the urban local bodies (ULBs) for urban roads was carried out. A case study based approach has been adopted to analyse the maintenance management practices in three urban local bodies. The case study analysis indicates the absence of structured process for prioritizing maintenance of urban roads. A model has been developed for prioritizing the maintenance of urban roads using fuzzy logic approach. The findings of this research study would help the officials of ULBs to allocate constrained resources in more effective manner and ensure better quality urban roads.

Keywords: Maintenance Management, Urban Roads, Urban Local Bodies, Fuzzy Logic

1. Introduction

Road network is one of the important factors that contribute to the economic growth of any country. It is imperative for economic progress that roads are well laid out and maintained. Although the Indian road network is large, next only to the road network in the United States of America, an underlying problem is the quality of roads. Roads are often poorly maintained, leading to delays and disruption in traffic, environmental pollution, and inefficiencies in economic transactions.

According to a report published by High Powered Expert Committee (HPEC), constituted by the Government of India for estimating the investment requirements for urban infrastructure services, an investment of USD 82.67 billion(2009-10) and 44% of investment in urban infrastructure are required over the next twenty years for improving urban roads (Ministry of Urban Development, 2011). The achievement of objectives of any infrastructure depends not only on construction of the asset but also on quality maintenance of the created asset. The HPEC's report mentions that only 1.7 % of per capita investment on urban roads is spent on maintenance in India. This compromises on the life of the asset and fails to earn the value of investment on asset creation.

In India, the responsibility of urban road maintenance lies with the urban local bodies (ULBs). The poor maintenance management practices among ULBs have been often mentioned as the reason for the current poor state of Indian urban roads. In this context, a research study was carried out to understand the road maintenance management practices followed by ULBs and develop a model for the prioritized maintenance of urban roads in India. This paper describes outcomes of this research study.

2. Research Methodology

The research methodology for this study comprised literature survey, case study, questionnaire survey and modelling with fuzzy logic approach. A review of literature was first performed to understand the current practices among ULBs for maintenance of urban roads and best practices, decision frameworks and models for urban roads. This was followed by case studies of maintenance management practices in three ULBs in the state of Gujarat. The primary objective for these case studies was to understand how the urban local bodies undertake the maintenance management of urban roads and analyse these processes from a theoretical angle provided by the framework discussed in section 3. The challenges faced in adoption of systematic process for maintenance management of urban roads were also identified.

Three ULBs in the state of Gujarat, India were selected. These three urban local bodies are among three prominent cities in the state. These ULBs were selected on the basis of parameters like urban population, geographical area, length of urban roads, capital expenditure of ULBs and financial allocation towards construction and maintenance of urban roads. The profile of these three ULBs is shown in Table 1.

Table 1 Profile of ULBs

Sr No	*Aspects*	*ULB – A*	*ULB – B*	*ULB – C*
1	*Population [No]*[1]	*55,70,585*	*44,62,002*	*16,66,703*
2	*Area [sqkm]*[2]	*464.16*	*326.515*	*159.95*
3	*Length of Urban Roads [km]*[3]	*2399*	*2874*	*1000*
4	*Administrative and Political units of ULB responsible for road construction and maintenance*	*Road & Building Committee [E], Road Project Department [A], Road Department [Z]*	*Standing Committee [E], Road Development Department [A], Road Department [Z]*	*Standing Committee [E], Road Project Department [A], Road Department[Z]*
5	*Capital expenditure of ULBs [Million INR] (2013-14)*	*20750*	*16251*	*2612*

[E]: Elected Wing, [A]: Administrative Wing, [Z]: Zone Level,1 USD = 66 INR, 1: Year 2011 (Census of India, 2011), 2: Area under the jurisdiction of ULB, 3: In the year 2011

All these ULBs are from the state of Gujarat and therefore suited a natural comparative multiple case study research design. These ULBs shared similar policy environment and procedures at the state level, but differed in parameters such as organizational structure, aspirations of political members and ULB officials, organizational procedures and practices, and road infrastructure assets. Therefore, our case study design provided natural controls of the study as well as environment for analytical generalization and theory building.

The data pertaining to case studies was primarily gathered by semi structured interviews with the officials of ULBs, and this data was supplemented and supported with the information gathered from municipal manuals, archival records, websites of ULBs, contract agreements, organizational policies and guidelines pertaining to maintenance practices in selected ULBs. The interviews were recorded and further transcribed. The transcripts were analysed with the NVIVO software, and the analysis involved "axial coding" – line by line coding of transcripts, gathering of similar information under different themes and preparation of final themes by merging and consolidation of related themes. Table 2 provides background of interviewees. In total, 18 interviews were carried out in three urban local bodies. The themes that has emerged from the analysis of these interviews are discussed in Section 4.

Table 2 Information about Interviewee

Sr No	*ULB*	*Level of Authority*	*Designation*	*Number*
1	*ULB-A*	*Top Level*	*Additional City Engineer*	*1*
		Middle Level	*Assistant Engineer*	*4*
		Bottom Level	*Technical Supervisor(2), Budget Department Employee (1)*	*3*
2	*ULB-B*	*Top Level*	*Chief Accountant*	*1*
		Middle Level	*Assistant Engineer*	*2*
		Bottom Level	*Technical Supervisor*	*1*
3	*ULB-C*	*Top Level*	*Budget Head, Additional City Engineer*	*2*
		Middle Level	*Assistant Engineer*	*3*
		Bottom Level	*Technical Supervisor*	*1*

The last step involved development of a model for the prioritisation of urban roads for maintenance. Fuzzy logic along with MATLAB software was used for modelling. Three road networks from these ULBs were selected for the application of this model. The process for the development of model is as follows:

1) The earlier two steps – literature review and case study analysis assisted in the identification of factors for prioritization of urban roads and modelling these factors,

2) For defining inputs, data collection was done based on two questionnaires for 'Importance of the factors' and 'Importance of the factors with respect to roads', and

3) Fuzzy logic was applied in two stages for the responses of the officials to achieve the prioritisation of the urban roads for maintenance.

- Stage 1 – Application of fuzzy logic for officials' responses for 'Importance of the factors' as well as for 'Importance of the factors with respect to roads'.
- Stage 2 – Application of fuzzy logic for Stage 1's outputs with reference to particular urban road network for carrying out prioritization of roads for maintenance operations.

3. Maintenance Management for Urban Roads

As part of the first step of this research study, literature was surveyed in order to analyze the various processes involved in the maintenance management of urban roads. The maintenance management has been conceptualized from process perspective with steps like deciding objectives of road maintenance, assessment of road performance, planning and decision making, and interventions to be adopted for road maintenance. These steps are not necessarily sequential in nature; rather there is cooperation and coordination required among them for effective maintenance management. The identified processes are presented in Figure 1 and briefly as follows.

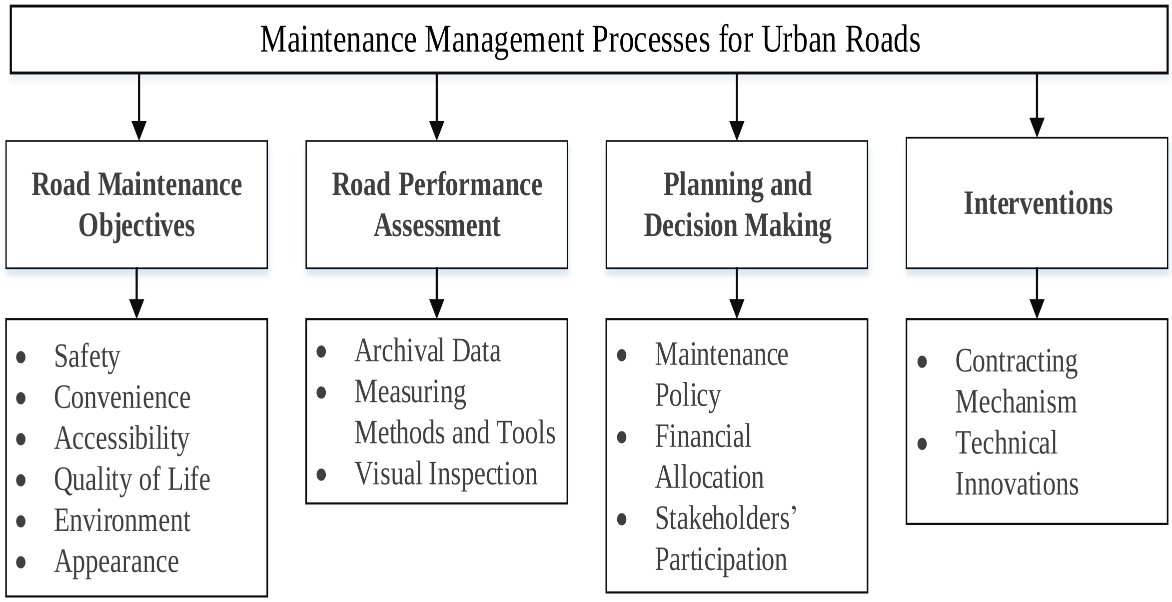

Figure 1Maintenance Management of Urban Roads

The road maintenance objectives elaborate the reasons behind undertaking road maintenance (Schraven et al 2011; Adey et al 2014). The ULB deciding the maintenance strategy for urban roads may pursue single or multiple objectives. The challenge faced by ULB is to strike a balance between these varying objectives. Safety and accessibility can be primary objectives which are required to be fulfilled by any ULB because they emphasize on the basic requirements for human accidents and road connectivity. Convenience and appearance focus on the quality of the road and the operational efficiency (impacts of the road quality on vehicles' performance). The management of traffic as well as road conditions result in good quality of life. Environmental considerations focus aspects like noise and air pollution.

Road performance assessment is typically undertaken to understand the conditions of existing road infrastructure asset and the outcome of this assessment provides valuable suggestions for deciding future courses of action (Schraven et al 2011; IRC 1989). The archival data that includes age of the roads and the past operations that were carried out on the roads as a part of maintenance must be analyzed. The performance measurement can be carried out with visual inspection and / or measurement methods or tools. Visual inspection includes recording the details of maintenance requirement based on the visual observation while measure methods and tools uses advanced road pavement monitoring equipment for assessing damage and its intensity.

Planning and decision making is important as it formulates the philosophy for the maintenance works (Sharma and Vohra 2009; Too 2012; Osman and Nikbakht , 2014). The rules and standards for maintenance work are decided based on the maintenance policy formulated and adopted by the ULB. There are diverse sets of stakeholders involved in both policy formulation and implementation. Therefore, the technical system of maintenance management, which is the focus of processes like deciding maintenance objectives and road performance assessment, is intertwined with the social system involving asset managers, users and political decision makers. Based on the maintenance policy and stakeholders viewpoints, financial resources are allocated for the maintenance of urban roads. The interaction between the above three processes, results in the design and implementation of appropriate intervention strategies. These interventions aim to maintain quality of asset and provide targeted user benefits (Sharma and Vohra 2009; Too 2012). It involves the use of contracting mechanisms like percentage rate contract, performance base contract etc. and new innovations like polymeric roads, micro surfacing etc.

4. Case Study Analysis

4.1 Collaboration between actors involved in the socio technical system

The evidence from the case studies indicates that the process of maintenance management is complicated by the involvement and interaction of multiple stakeholders. The effectiveness of this process hinges on identifying the urban road as a "socio technical system" and striking a balance between expectations of different stakeholders. Osman and Nikbahat(2014) discussed the complex interactions that occur between the agents like roadway users, asset managers and politiciansfor roadway performance and asset management. They have modelled these interactions with game theoretic approach, indicating how behaviour of various agents involved in the asset management impacts their collective decision making behaviour. Similar scenarios have also been observed with "cooperative as well as non-cooperative game" between different set of stakeholders. The influence of politicians in the sphere of selection of roads for maintenance and fund allocation prominently emerged in the case analysis. Often, this influence is contested by the administrative officials of the ULBs. The dislike towards undue influence of politicians in the decision making process was aptly narrated by an official of ULB – A:

"Political involvement also plays significant role in prioritisation but that doesn't mean that the road is not required to be prioritised. We don't adopt the suggestions of political parties if road is really not required to be maintained."

The absence of meeting of minds of politicians and technical persons was summed up by the ULB – A official:

"I want to tell you that ideally requirement should be generated by technical department and not by any political corporators at zonal level but still the situation is the same only. There are many roads which we have made according to our technical knowledge avoiding the suggestion by the political councillors."

Although, there was a common agreement between these important decision makers – politicians and administrators–over collecting feedback from the road users for understanding maintenance needs, there was disagreement over the question of whose opinion would have a final say in the maintenance management process. This non-cooperation observed between asset managers and politicians over the prioritization of urban roads for maintenance stems from the lack of appreciation of urban roads as a "socio technical system". This often results in undue delays and short sightedness in the decision making process.

4.2 Policies and guidelines required for effective maintenance management

The policies for maintenance management of urban roads help in articulation of strategic goals and charting out procedures to achieve these goals. The case study organizations have been following set procedures for the maintenance of urban roads; however, these procedures lack strategic orientation and direction. The interviews with the ULB – A, B and C officials revealed that there is lack in clarity over the objectives to be pursued for the maintenance of urban roads and they were considered implicit part of any maintenance approach. As a result, the benchmarks for assessing effectiveness of maintenance strategy were often either not set or vague. All ULBs expressed that they sought guidance from the manuals prepared for maintenance by National Highway Authority of India (NHAI) and Ministry of Road Transport and Highway (MORT&H). However, lack of particular policy and / or manual for the maintenance of urban roads was mentioned as a key impeding factor by many interviewees from these ULBs. Diverse views over maintenance objectives among the officials of a single case study ULB and financial constraints faced by these ULBs necessitate the clarity over maintenance objectives. An official of ULB – A mentioned the objective for maintenance and its effectiveness as follows:

"See, when we talk about the urban roads they already have thickness of 1m. So, there base is very strong. They just require there riding surface to be appropriate. Yes but one thing is very important and that is quality of maintenance. If quality of maintenance is improved then many issues can be resolved."

Most of our interviewees mentioned improvement of "quality of riding surface" as a maintenance objective, with a little or no mention about the other objectives like accessibility, convenience, quality of life and safety. Scharaven et al (2011) stressed the importance of formulating "infrastructure objectives" before undertaking maintenance by public agencies. They postulated that clarity on infrastructure policies and objectives would result in 1) devising of appropriate maintenance strategies, 2) formulation of indicators and maintenance norms for assessing effectiveness / performance of maintenance strategy, and 3) cost efficiency in maintenance management.

The absence of maintenance policy also affects allocation of financial resources. The construction of new roads gets priority over maintenance of existing roads during allocation of financial resources. This clearly shows that budget for maintenance is not satisfied considering the requirement of the new construction. This results in poor life cycle of the created asset. A comparison of financial resource allocation towards construction and maintenance of roads in three ULBs (Refer Table 3)shows that despite increase in construction of new roads, maintenance is not prioritised and/or focused as required. The backlog in allocation of financial resources is higher in the case of ULB-A and ULB-C. In case of ULB-B, construction of roads as well as maintenance has increased over time. Therefore, design of maintenance policies and objectives in the case study ULBs is essential.

Table 3. Financial budget for construction and maintenance of urban roads

Year	*2010-11*	*2011-12*	*2012-13*	*2013-14*

4.3 Role of private sector in maintenance management needs to be managed effectively

The construction and operation of highways in India has seen a gradual shift towards increased private sector participation with contracting mechanisms like build operate transfer (BOT), annuity contracts and engineer procure and construct (EPC) contract. Similar trends were observed in the case study organizations with increased participation of private contractors. Traditionally these ULBs have been undertaking maintenance of urban roads with in-house equipments, labour and technical personnel. However, over the years, these ULBs have changed the approach and now different contracting mechanisms are adopted for private sector involvement. This transition in the contracting mechanism was shared by an official at ULB-C as follows:

"Another important thing I want to add is that before 10years works have been done in house. Outsourcing is invited from 10 years only. Now as a packaged and performance based contracts are given to the contractors."

Small maintenance jobs are executed with in-house resources while large maintenance activities are undertaken with private sector participation. Two contracting models in these ULBs were primarily used: percentage rate contract and performance-based contract. Performance-based contract encourages technical innovation of private sector with the use of techniques like micro surfacing, milling process, polymeric roads, etc. The adoption of technical innovations for the maintenance of urban roads was summed up by an official as ULB-B as under:

"In recent past we have done experiments on it. With the help of plastic waste we have constructed the roads. Now we are checking the performance. Another thing which we are doing is micro surfacing. Sometimes the only upper layer of the road has get deteriorated that doesn't mean that we will construct the whole road again."

The case study evidence indicates that the primary reason behind increasing involvement of private sector in maintenance of urban road was improved quality and cost effectiveness. However, it is important to note that the capacity of ULBs to manage these innovative contracting and technical mechanisms is a central factor for achievement of benefits with private sector participation. Too (2012) mentions this capacity as "technology absorptive capacity, i.e. the ability to embrace and capitalise on new technologies to enhance their maintenance management process. Our analysis shows differences in the "technology absorptive capacity" among the ULBs. ULB-A and ULB-C lag in the adoption of innovations due to constraints such as lack of skills to investigate feasibility of carrying out these works, absence of financial resources and so on. Although ULB-B has adopted performance-based contracts to a larger extent, the capacity to monitor and assess benefits from these contracts is lacking. Therefore, these ULBs must initiate steps towards creation of technology absorptive capacity, as mentioned by Too (2012), in the immediate future.

5. Development of Road Maintenance Management Model

The case study analysis of the three urban local bodies indicated the need for structured approach towards maintenance management of urban roads. The third stage of this research study focused on development of road maintenance management models. This stage can assist decision makers in urban local bodies in the selection of appropriate urban roads for maintenance.

A literature survey has been carried out focusing on different modelling methods for road prioritization. This led to the selection of the fuzzy logic approach for the maintenance model. Although fuzzy logic was developed in 1965 as a part of soft computing research, the method gained attention only after a decade. In spite of having roots of soft computing, fuzzy logic has been widely used as a prioritisation model. Tah and Carr (2000) have studied construction project risk assessment using fuzzy logic. In this model, severity of the risk is first derived and then the probability of their occurrence is analyzed. Fuzzy logic is used to map the input with the help of realistic output. When the ratings given to the various factors do not include the probability of the consideration of these factors, they do not provide a realistic approach. Fuzzification of these ratings considers the importance of these factors as well as the probability of them falling in the criteria for that rating. Probability of occurrence is measured by different membership function in fuzzy logic. The same approach can be applied in this research, where in fuzzy logic is used to know the importance of the factors for the prioritization of urban roads for maintenance. Then, for particular road networks, significance of these factors can be derived for establishing prioritization of urban roads. A literature survey has been carried out for the identification of factors for the prioritization of urban roads for maintenance. The case study analysis carried out in the previous step helped in refining and grouping factors that emerged from the literature survey. There are 12 factors in total which are grouped into five categories: social, decision makers, environment, maintenance operations and their impact, and road performance assessment (Table 4). Three road networks from the ULBs, that formed the part of analysing maintenance management practices, were selected for the application of model for prioritising the roads for maintenance operations.

5.1 Fuzzy Modelling

5.1.1 Data collection

The responses of officials associated with the maintenance of urban roads in these three ULBs were collected in the form of questionnaires.

Questionnaire 1 - Importance of the factors: The objective of this questionnaire was to know the importance of these factors from the viewpoint of officials who are only responsible for road prioritization.

Questionnaire 2 - Importance of factors with respect to roads: The reason behind conducting this questionnaire survey was to consider the importance of the factors for a particular road network for prioritising maintenance of different roads.

Table 4. Factors for prioritization of urban roads

5.3	*Road Condition*	*Y*	*Y*	*Y*	*Y*	*Y*

Y: Yes; N: No

5.1.2 Fuzzification

The ratings collected by officials were first fuzzified in order to achieve sharp output. Ratings by the officials have certain probability of occurrence which was achieved by their fuzzification. These inputs were fuzzified with the help of Gaussian curve membership function, which can generate a smooth input. For applying rules for fuzzification, "and" function was used. The function takes the minimum value of the all inputs at is the optimum rating given to it. This function defuzzifies it with Gaussian Curve Membership Function.

Gaussian Curve Membership Function (Gaussian Curve Membership Function, MATLAB- gaussmf)

y = gaussmf(x,[sig c])

The symmetric Gaussian function depends on two parameters σ and c as given by

$[\![-(x-c)]\!]^2/(2\sigma^2)$,$f(x;\sigma,c)=e$

The parameters for gaussmf represent the parameters σ and c listed in order in the vector [sig c].

5.1.3 Defuzzification

In order to achieve a sharp output, the rankings given by the officials had to be defuzzify. The triangular-shaped membership function was used for this. The centroid of this triangular membership functions were considered and output was generated. Based on the ratings given by this triangular membership function, ratings were considered for prioritization of urban roads.

Triangular-Shaped Membership Function (Triangular-Shaped Membership Function, MATLAB- trimf)

y = trimf(x,params)

y = trimf(x,[a b c])

The triangular curve is a function of a vector, x, and depends on three scalar parameters a, b and c as given by,

$$f(x;a,b,c)=\begin{Bmatrix} 0, & x\le a \\ \frac{x-a}{b-a}, & a\le x\le b \\ \frac{c-x}{c-b}, & b\le x\le c \\ 0, & c\le x \end{Bmatrix}$$

Or more compactly by,

$$f(x;a,b,c)=\max\left(\min\left(\frac{x-a}{b-a},\frac{c-x}{c-b}\right),o\right)$$

The parameters a and c locate the “feet” of the triangle and the parameter b locates the peak.

5.1.4 Application of Fuzzy Logic in MATLAB

Fuzzy logic was applied in two stages to analyse the importance and impact of the factors for road prioritisation for maintenance. *Stage 1 (Part 1):* Ratings collected from questionnaire 1 were fuzzified. The fuzzification of these inputs provides the importance of the factors irrespective of roads on which the model would be applied.

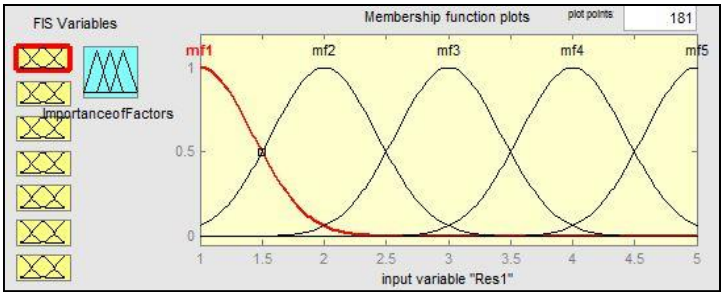

Figure 2. First Stage (Part 1) Fuzzy Structure

Stage 1 (Part 2): Ratings from questionnaire 2werefuzzifiedto know the impacts of the factors with respect to roads of that particular road network.

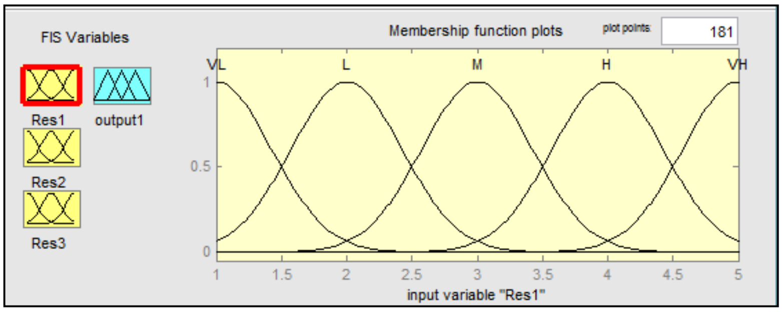

Figure 3. First Stage (Part 2) Fuzzy Structure

Stage 2: Outputs from Stage 1 (Part 1 and Part 2) were considered as inputs here, and fuzzy logic was applied to give the fuzzified ratings for the factors with respect to their importance and the impacts with respect to the roads. The fuzzy output gave the impact of every factor generated on the roads of this road network. Roads with highest number of the factors having highest were prioritised as they have the highest requirement of maintenance.

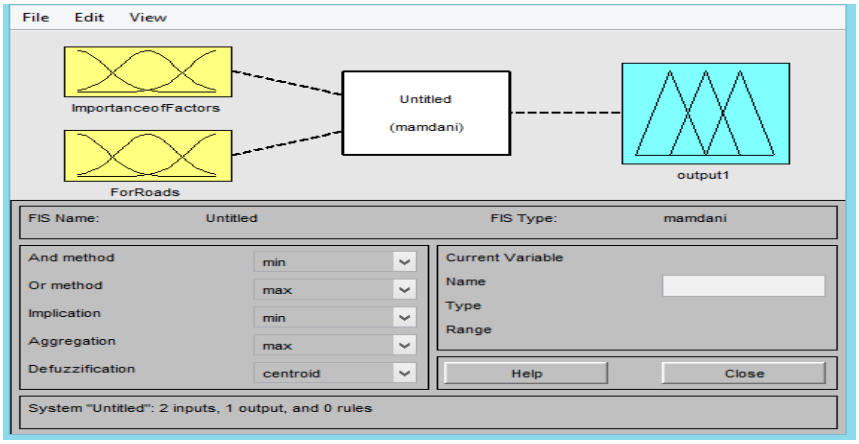

Figure 4. Second Stage Fuzzy Structure

6. Conclusions

Case study analysis indicated that ULBs face challenges on various fronts while carrying out the maintenance management of urban roads. These challenges can be broadly categorized under different themes like collaboration between stakeholders, need for maintenance management policies and guidelines and capacity for managing involvement of private sector. The ULBs and development actors must initiate strategic steps for addressing these challenges. The prioritization of urban roads for maintenance is the central theme for maintenance management processes, which becomes very complex owing to expectations of different stakeholders. The factors identified for the prioritization of urban roads in this research study along with the maintenance management model would help decision makers in systematically arriving at a decision to select appropriate roads for maintenance. This model would not only assist in meeting immediate needs of roads prioritization but also systematize the entire process of maintenance management.

Construction Entities Tracking Based on Functional Integration and Online Learning with Site-customized Datasets

Jinwoo Kim, Seokho Chi and Taekyoung Kwon

Seoul National University, Korea
Email: jinwoo92@snu.ac.kr

Abstract

In construction domain, visual tracking of construction entities has received high attention and many researchers have investigated tracking methods. Although previous methods showed promising results, it has still limitations to reflect various characteristics of construction sites and entities: dynamic movements and various conditions (shapes, colour, type). One of the most common methods is tracking with probability, but it is sensitive to abrupt shape/scale changes and dis/re-appearances of objects. For the other methods based on pre-trained detectors, it is impractical to collect training datasets for all possible conditions such as entity types, colours and shapes. To deal with such shortcomings, a novel tracking method based on functional integration and online learning was proposed in this paper. Functional integration enables to track a target object under its dynamic movements by running a detector and a tracker at the same time. Online learning is able to reflect various characteristics of a target object developing site-customized datasets in real-time and automatically. The proposed method was validated with the video data recorded from the real construction sites. The results showed it has a high potential for tracking construction entities with 87% of a precision and 86% of a recall rate. It was possible to track a target object under its dynamic movements for various object types and their different colours and shapes. With the acceptable tracking performance, visual analyses on construction sites can be improved.

Keywords: Vision-based, Tracking, Detection, Functional integration, Online learning, Site-customized datasets

1. Introduction

On construction sites, a number of construction entities (e.g. workers, equipment) are scattered within the limited area; thus, unexpected events such as safety accidents occur frequently. The needs for on-site information have increased to manage the crowded and busy working environments effectively and efficiently. In detail, site information such as input entities, work in progress, and working/idle time can be used for the productivity and safety analyses (Gong and Caldas, 2010; Memarzadeh et al., 2013).

To collect site information, direct observation or survey/interview-based methods have been commonly performed. However, such methods revealed the following limitations; error-prone, time-consuming, and expensive processes (Navon and Sacks, 2007; Gong and Caldas, 2010; Chi and Caldas, 2011). To overcome such shortcomings, real-time vision-based site monitoring systems have been proposed due to its potential to extract various site information automatically and support decision making in project management (Chi et al., 2009; Chi and Caldas, 2011; Gong and Caldas, 2013; Memarzadeh et al., 2013; Golparvar-Fard et al., 2013).

To produce meaningful information from video streams, a high performance tracking should be acquired: the essential information including locations and types of the target entities can be generated from tracking processes. Moreover, the tracking can provide additional information for enhancing project management performance such as working type, idle/working time, and other productivity or safety related movements (Memarzadeh et al., 2013; Golparvar-Fard et al., 2013).

In response to the needs of tracking methods, many researchers have investigated tracking methods for construction entities. However, they have a low applicability due to a difficulty of reflecting various characteristics of construction sites and entities. It easily fails to track a target construction entity when it moves dynamically, and it is impractical to develop datasets that includes all possible conditions on construction sites. To overcome the limitations, this paper proposes a novel tracking method based on functional integration and online learning. It is expected that functional integration is able to track a target object under dynamic movements and online learning enables developing site-customized datasets.

2. Literature Review for Problem Setting

Many tracking methods have been investigated to understand site conditions more accurately. Tracking algorithms using Kalman filters or particle filters were simple and popular methods for object tracking (Hue et al., 2002; Yilmaz et al., 2006). Chi et al. (2009) presented the tracking method based on the background subtraction and pre-trained classifiers. A point matching method was suggested to track construction workers and equipment (Brilakis et al., 2011). Colour and spatial modelling algorithms were also proposed by Park and Brilakis (2012). Such tracking methods can be categorized into two main approaches: tracking with probability and tracking by detection (Yilmaz et al., 2006). Tracking with probability methods infer the posterior movements (e.g. location, velocity, and acceleration) of target objects with the comparison to their priori movements. It is performed with user initialization in the first image and it does not need any pre-training process. However, the algorithms are sensitive to tracking failures such as shape/scale changes of objects and dis/re-appearances after in and out from the camera's field of view and occlusion of target objects (Yilmaz et al., 2006). In contrast, tracking by detection methods are relatively robust in handling those failing cases since they use pre-trained detectors. However, to train a robust and powerful detector, various datasets and time-consuming tasks are required. In addition, the quality of dataset significantly determines the detector performance (Dollar et al., 2009; Benenson, 2014). Furthermore, tracking by detection methods are not able to realize objects that are not presented in the training dataset.

Although the previous tracking methods showed the acceptable results, it has a difficulty to reflecting the characteristics of construction sites and entities. The characteristics are represented by two main factors: site conditions and entities. First, surrounding conditions—which should be considered as the background in the detection and tracking process—vary on sites. Different types of equipment appear on different sites (Figure 1), which means that target objects to be tracked are difficult to be decided in advance. Second, each entity has high intra-class variations. Concretely, not only the same type of equipment has diverse colours and appearances but also appearances and shapes of the same object can change due to different working postures and camera's viewpoints (Figure 2). Moreover, the entities are easily disappearing or re-appearing because of occlusions and moving in and out of a single camera's view.

Those characteristics of construction sites and entities reveal practical limitations of the previous tracking methods. When developing training datasets for tracking by detection, it is very impractical to include all possible conditions of different surrounding conditions, various types of equipment, and high intra-class variations. In other words, it is labour-intensive to pre-collect training datasets to satisfy all possible working conditions. In case of tracking with probability, it is difficult to handle shape changes and re-/dis-appearances effectively. In summary, the most of previous tracking methods in construction have limitations to reflect the complex characteristics of real construction sites. This paper presents a novel tracking method based on functional integration and online learning with site-customized datasets. The proposed method is expected to have high potential for the long-term tracking under the dynamic working environments as well

Figure 1: (a-1) Trucks from site A. (a-2) Excavators from site A. (b-1) Truck from site B. (b-2) Excavators from site B. (c) Truck from site C.

as re-tracking in case of dis/re-appearances. It is also applicable to unknown objects developing training datasets in real-time and automatically.

3. Technical Development

The proposed method is composed of two main concepts: 1) functional integration of a detector and a tracker and 2) online learning with site-customized datasets. The details for each concept are described in the following sections.

3.1 Functional Integration of a Detector and a Tracker

Functional integration is a process of running a detector and a tracker at the same time and determining final results as comparing and analysing their results. The detector functions independently in each frame, finds a target object, and it offsets effects by shape/appearance/scale changes; however, it requires a time consuming pre-training step. The tracker estimates locations of a target object considering the object state in a moving condition such as velocity, location and shape among the consecutive image frames (Kalal et al., 2012). Thus, it easily fails and is not able to recover when the shape/appearance suddenly changes and an object moves out of camera's field-of-view or re-appears after occlusions. To share their advantages and reduce shortcomings, a combined detector and tracker was designed to act at the same time as shown in Figure 3. The errors can be corrected by each other. The sensitiveness of the tracker to occlusions, re-appearances, and abrupt shape changes can be reduced by the application of the detector. The detector can be trained with the automatically labelled datasets from the tracking results. Such functional integration also helps to generate the effective positive (i.e., objects that should be tracked) and negative (i.e., background) samples during the detector training.

3.2 Online Learning with Site-customized Datasets

Online learning is a training or real-time learning process using the data that is updated while mapping tracked objects from corresponding labels in the dataset in sequential images (Shalev-Shwartz, 2011). There are two main differences from the offline learning. First, training dataset is produced from working environments where the object detector is applied. Second, it can be

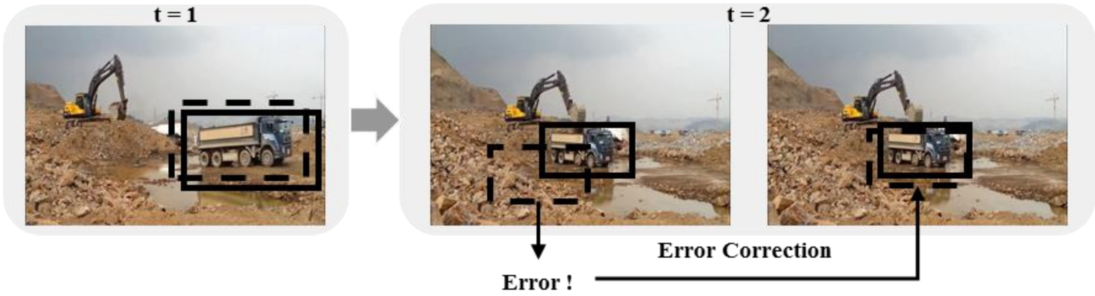

Figure 3: Error Correction Based on the Functional Integration a Detector and a Tracker.

Figure 4: Production Process of Initial Training Dataset.

applied for unknown objects. Based on the online learning, it is available to train a detector for any types and non-rigid objects by capturing datasets from the construction sites where the detector is applied; thus, the training datasets can be developed and customized by different site characteristics without a pre-collection process.

3.3 Framework of the Proposed Method

The framework of the proposed method is described in Figure 5. There are total three steps: 1) initialization, 2) functional integration and 3) online learning. Details of each step are described as follows.

Initialization. In the first image frame, initialization should be carried out. In Figure 4, a target object can be initialized with the bounding box by users, and the positive and negative samples for training datasets are produced online by considering the boxed area. The positive samples are extracted from shifting up/down/left/right the initialized box by 5% as shown in Figure 4. Contrary to the positive samples, the negative samples are generated in other regions in the image frame. Parts of the target object are not included in the negative samples, but it can be possible to have information related to non-target objects. After producing training datasets, the first step of online learning is performed to train and activate the detector. In case of tracking, tracking starts immediately after the initialization step is finalized.

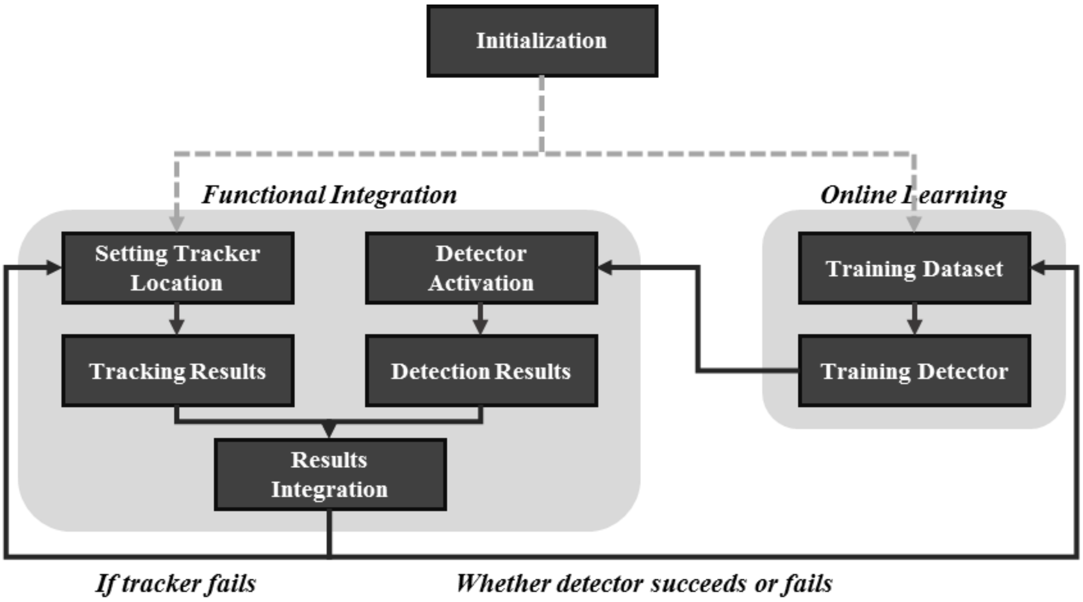

Figure 5: Framework of the Proposed Method.

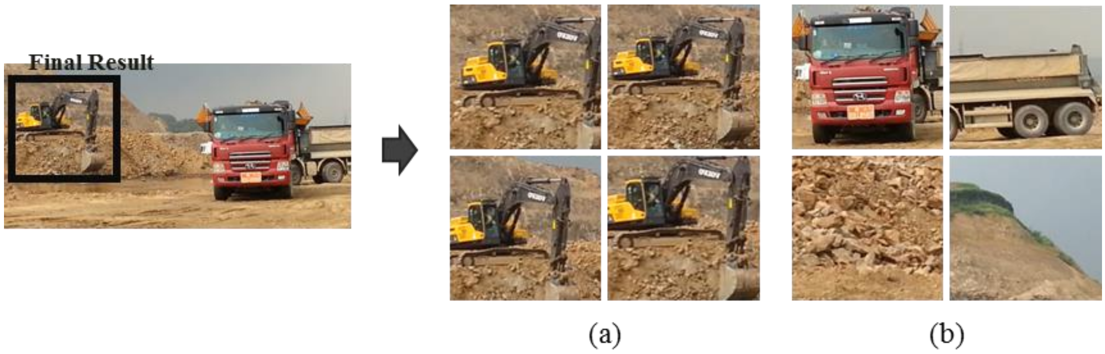

Figure 6: Dataset Example of Online Learning. (a) Positive samples. (b) Negative samples.

Functional integration of a detector and a tracker. Detection or tracking errors can be identified by comparing the results and their confidence. There are four cases: 1) both of them succeed, 2) both of them fail, 3) tracking fails and detection succeeds, and 4) tracking succeeds and detection fails. When both of tracking and detection succeed (the first case), the location and the size of the object are determined with the confidence and generates the black bounding box as shown in Figure 6. In contrast, when tracking and detection failed (the second case), the tracker stops to find an object and waits until the detector succeeds to find an object, and the searching area of the tracker is then reset by the detected information. It is possible because the detector scans all image pixels to localize a target object and performs independently in a single frame. This function enables to deal with dis/re-appearances caused by full occlusions or out-of-view movement. For the third case, the result of detection is accepted and searching area of the tracker is relocated at the detection area as explained previously. It allows the tracker to recover the target object. Finally, in the fourth case, tracking results are selected but the failure of detection is considered as the negative sample of the training datasets. However, the positive samples are extracted from the tracking results. Such technical approach that produces positive and negative samples makes the detector more robust.

Online learning with site-customized datasets. Based on functional integration of the detector and the tracker, the training datasets can be created. The detection can either succeed or fail. If the detection fails, the detected area is extracted for the negative samples to avoid similar errors. For the positive samples, the relocated area by tracking results can be assigned as the target object. Reversely, when detector localizes an object correctly, the detected area is selected for the positive samples and the negative samples are produced from the area except the detected area. The online learning based on the functional integration the detector and the tracker can customize the detector to the target object and background as shown in Figure 6.

4. Experimental Results

4.1 Data Collection and Description

To validate the performance of functional integration and online learning with site-customized datasets, the experiments were conducted with the video stream obtained from different construction sites where various types of equipment operated. Normal vision cameras were used for the data collection.

As shown in Figure 7, the collected datasets included various types of construction entities and working postures in different point views from four different sites. Occlusions and moving in and out of camera's field of view also existed and led tracking to become challenging. Total streaming time was about 45 minutes; the number of total frames was 64,968; and the resolution was 720 x 480. The proposed method was applied to unknown objects, which means that it does not need any pre-trained detector.

4.2 Quantitative and Qualitative Results

For the quantitative evaluations, the precision, recall rate and F-measure metrics were analysed. The precision is the number of true positives divided by the number of all responses, and it explains the reliability of the proposed method. The recall rate is the number of true positives divided by the number of target objects in all sequences. The high value of recall rate specifies whether the detector or the tracker works stable. The F-measure is calculated by the precision (P) and recall rate (R), 2PR / (P + R).

Table 1 summarizes the performance results. The processing time was 6 – 15 fps that satisfied eal-time processing. The average precision and recall rate were 87% and 86% respectively. It

(a) (b) (c) (d)

Figure 7: Examples of the Collected Dataset. (a) Dataset from site A. (b) Dataset from site B. (c) Dataset from site C. (d) Dataset from site D.

means that the proposed method has high potential for tracking construction entities, and the characteristics of sites and entities can be promisingly handled by the proposed method. Figure 8 and 9 shows the examples of the results. The bounding boxes were the predicted locations of the target objects. The Figure 8 explains the functional integration of the detector and the tracker that allows tracking the object in the long-term time frame. In Figure 8(a) describes the effects of error corrections. When the tracker/detector was about to miss the object, the detector/tracker relocated the tracking/detection position and it significantly reduced the sensitiveness to tracking/detection failures. Figure 8(b) is the dis/re-appearances. Although the truck re-appeared after out of camera's view, the proposed method was able to steadily re-track the target. It showed the robustness to dis/re-appearances and occlusions.

The results of online learning with site-customized datasets are illustrated in Figure 9. The datasets produced in real-time and online are illustrated in the left/right hand-side as the small image patches in Figure 9. With the site-customized datasets, the partial occlusion was able to be handled effectively as shown in Figure 10(a). Moreover, the difficulties of shape changes in different viewpoints were offset. As the backhoe rotated (the viewpoints change) as in Figure 10(b), the tracker kept localizing the backhoe correctly. In Figure 10(c), it showed the objects are kept tracking under the dynamic environment. Although the excavator had pose variations such as digging, hauling, dumping, and swinging, the method was able to maintain tracking with the application of the correction process.

Table 1: The Results of Performance Metrics

Metric / *Equipment Type*	*Precision*	*Recall Rate*	*F-measure*	*Processing Time*
Excavator	*0.8679*	*0.8654*	*0.8667*	-

5. Conclusions

This paper proposed a novel method that can track construction equipment in the long-term considering the unique and complex characteristics of construction sites and entities. The main components are 1) functional integration of a detector and a tracker and 2) online learning with site-customized datasets. The results showed the high potential for tracking various types of equipment under dynamic construction environment. With the acceptable tracking performance, it is available to achieve visual analyses on construction sites. However, the study can be still further improved with the following issues. The first issue is an expansion to multi-target tracking. For application on real construction sites, multi-target tracking should be implemented. Second, the proposed method should be applied to more various types of construction entity.

Relevance of Five Generic Business Ideation Approaches vis-à-vis Contexts Embedded within Construction Markets

Pekka Huovinen

Construction Management and Economics, Tampere University of Technology, Finland
Email: pekka.huovinen@tut.fi

Abstract

In general, ideation encompasses the formation of ideas or mental images of things not present to the senses or simply the creation of new ideas**.** Business ideation is herein perceived to be the core area within future-oriented business management (BM). The main aim of the paper is to assess and advance the relevance of the five generic approaches to business ideation vis-à-vis firms targeting contexts embedded within construction markets. A typology differentiates between the fitting, value-creating, profit generating, systemizing, and commercializing approaches. It is argued that each approach is, at minimum, highly relevant in the case of business unit (BU) management targeting preferred client investment and procurement behavior within construction markets. Approach 1 involves BUs aiming at fit between clients and their needs as well as units' offerings and operations, respectively. Professional clients couple needs with preferred procurement methods whereas competing BUs are trying to achieve best fit between solutions and client behaviors. This approach calls for research on how to sustain such fit between a BU and clients when changes occur. Approach 2 enables BUs to create value by specifying high-value propositions, producing value to clients, and capturing their fair shares of produced values. Farsighted clients look for more or novel values for construction investments and, thus, units are collaborating and co-producing values to clients. This approach calls for research on a BU's value co-production with such clients, value capture, and offerings integration. Approach 3 accommodates BUs that are focusing on generating profits, achieving high-profit levels, and sustaining them. Pioneering clients pursue complex investment aims that can be met only by radical solutions. This approach calls for research on a BU's profit-generating mechanisms related to clients with complex investment needs and radical solutions. Approach 4 facilitates BUs to systemize businesses around core ideas. Sectoral clients have large or complex needs and, in turn, units are satisfying them by engineering systems as wholes and delivering them as parts. This approach calls for research on BUs with systems and clients, multi-dimensional investments, and system engineering as wholes and parts. Approach 5 facilitates BUs to couple ideas with commercializing dimensions such as entrepreneurship, innovation, business development, venturing, or spin-offing. Risk-taking clients prefer to enter high-innovation contracts and, thus, units are offering novel solutions and emerging business cases. This approach calls for research on a BU's entrepreneurial competencies and risk-taking clients, wicked investment needs, and high-innovation contracts. In the same vein, the suggestions are put forth to CIB-related scholars for directing research on along the BM and ideation dimensions and adopting most relevant approaches. Likewise, management in firms and BUs competing in construction markets are encouraged to assess the business case-sensitive relevance of each of Approaches 1-5 and try out those with initial high relevance.

Keywords: Business ideation, business management, construction markets, literature review, management concepts

1. Introduction

Managing a single business (un)successfully is herein seen the most fundamental area of strategic management. In the same vein, *business management (BM) research* is perceived as the most important and evolving sub-field within strategic management research. Within the BM scope, the focus is on managing business issues. In general, ideation encompasses the formation of ideas or mental images of things not present to the senses or simply the creation of new ideas (OED 2012)**.** Business ideation is herein perceived to be the core area within future-oriented BM. The *focal contexts* are embedded within *construction markets*, i.e., the contracting, design, construction, servicing, project-based, and life-cycle aspects of capital and construction investments in natural resources usage, energy supply, telecommunications, transportation, infrastructure, manufacturing, general building, and other real estate concerns.

This paper is part of the pioneering reviewing of construction-related BM research (e.g., Huovinen 2003a, 2006a-b, 2015a-c). The *nature* of this paper is that of reporting on the conduct and findings of a *focused review* of relevant published, conceptual knowledge about business ideation as part of BM. The rationale is that advancements can be designed based on the revelation of the current states of business ideation affairs via a review of the 71 construction-related BM concepts that have been published via the formal channels between 1990 and 2013. The *main aim of the paper* is to evaluate and advance the relevance of the five generic approaches, i.e., the fitting, value-creating, profit-generating, systemizing, and commercializing business ideation vis-à-vis firms and their business units targeting contexts embedded within construction markets. Accordingly, the *three sub-aims* are as follows:

- How is the reviewing being conducted? What are the degrees to which the authors have designed their 34 (out of 71) construction-related BM concepts along the business ideation dimension? The focused review is reported upon in Section 2.
- What are the generic Approaches 1-5 to business ideation? How relevant is each of them in the case of business unit (BU) management vis-a-vis business ideation with contexts embedded within targeted construction markets? Approaches 1-5 and 13 high-degree concepts are briefed as well as the approach-specific relevance is assessed in Section 3.
- How to advance the relevance of Approaches 1-5 vis-à-vis managing business ideation related to contexts within construction? The suggestions are put forth in Section 4.

2. Reviewing of Construction-Related BM Research

2.1 Four reviewing rounds between 1999 and 2014

The four reviewing rounds have been carried out in 1999-2003, 2006, 2010-2012, and 2014. Cooper's (1998) approach and the same limitations have been re-adopted to protect the validity. *The coherence* has been maintained by focusing on research on firms based in the OECD countries. Exceptionally, references originating from Singapore and Hong Kong have been included due to the authors' British Commonwealth heritage and research on international construction. Hart's (1998) guidelines have been relied upon. The design of the *method for the reviewing of conceptual research*, i.e., the replicable handbook-based and invented-here ways have been documented, used, and reported upon in Huovinen (2003a, 2006a-b, 2013 and 2015a-c). The search for eligible concepts has been conducted comprehensively within the volumes of 21 journals in construction and those of 47 journals in business administration. Concerning the other channels, the degrees of the comprehensiveness vary. The reviewer submits the lists of all the channels on request. So far, the reviewing has resulted in the identification of 71 construction-related BM concepts that have been published between 1990 and 2013.

2.2 Focused review of business ideation as a dimension for designing 71 construction-related BM concepts

For the assessment, the *four degrees of the design of a particular construction-related BM concept along the business ideation dimension* were pre-defined as follows:

- *High degree*: A concept's primary parts include all the three core elements of business ideation, i.e., needs and clients, offerings, and operations and/or resources.
- *Medium degree*: A concept includes only one or two core elements.
- *Low degree*: A reference containing a concept only addresses issues in business ideation.
- *No degree*: A reference does not contain any explicit aspects of business ideation.

The assessment revealed that *48 % or 34 (out of 71) construction-related BM concepts include also the elements for managing business ideation*. There are *13 (18%) high-degree,* 6 (8%) medium-degree, and 15 (21%) low-degree BM concepts (Table 1).

Table 1: Four-degree assessment of the design of 71 construction-related BM concepts (published between 1990 and 2013) along the business ideation dimension.

High-degree business ideation No. (%)	*Medium-degree business ideation No. (%)*	*Low-degree business ideation No. (%)*	*No business ideation at all No. (%)*	*All construction-related BM concepts No. (%)*
13 (18)	*6 (8)*	*15 (21)*	*37 (52%)*	*71 (100)*

The assessment validity has been protected against the five biases as follows. *Concept Inclusion Bias 1* involves this reviewer perceiving that an author has designed a concept along the business ideation dimension even if this author has not done so. This bias has been minimized by assessing each reference in the same way and quoting only the necessary parts that contain 34 (48%) construction-related BM concepts designed along the business ideation dimension. Future reviewers can test the inter-concept consistency of inclusion by repeating the assessments, i.e., reading and confirming the same quotations or rejecting them. *Concept Exclusion Bias 2* involves this reviewer perceiving that an author has not designed a concept along the business ideation dimension even if this author has done so. 37 (52%) "no degree" assessments indicate that this reviewer did not identify business ideation. Future reviewers can test the inter-concept consistency of exclusion by repeating the assessments, i.e., reading and confirming the exclusions or identifying business ideation elements in them. After the inclusion, *Degree Assessment Bias 3* is related to this reviewer's reliance on a pre-specified scale of the three conceptual degrees instead of a quantitative scale. This reviewer could assign one of the three pre-defined degrees to each of 34 concepts without hesitation. Future reviewers can test the inter-concept consistency of degree assignments by reading and confirming the same degrees or assessing changes in them. Or, they could re-specify a scale of degrees. *Concept-Approach Correspondence Bias 4* is related to the mapping of each of 13 high-degree concepts onto one or more business ideation approaches (Table 2). This reviewer could map each concept onto one generic business ideation approach based on the identification of the theoretical roots and elements. Future reviewers may deepen this analysis, e.g., by itemizing each (sub-)element within the references and quoting them in a set of more detailed tables to allow cross-approach comparisons and correspondence identification. *Concept Author-Reviewer Bias 5* is related to a fact that this reviewer has designed 14% or 10 (out 71) concepts. 7 (out of 10) concepts have been designed along the business ideation dimension. Thereof, this reviewer assessed that he has designed 3 high-degree, 1 medium-degree, and 3 low-degree concepts. Future reviewers can test the inter-concept consistency of the assessment outcomes versus each of the four other biases in the case of 10 concepts designed by this reviewer.

3. Five Generic Business Ideation Approaches

In general, OED (2012) defines that "*to idea* is to give a particular form or character to…". In turn, *ideation* encompasses "the formation of ideas or mental images of things not present to the senses" or simply **"***the creation of new ideas***".** Aligning with Normann's (2001) root principle of fit, a *business idea* is herein defined to consist of the three core elements, i.e., a focal firm is (i) targeting an environment with potential clients and their needs, (ii) developing and leveraging its offerings that best satisfy targeted needs, and (iii) organizing a BU and, thus, performing operations, enabled by its resources.

How is business ideation being approached within strategic management literature? Previously, this author has identified and differentiated between the *five generic approaches* to business ideation, i.e., fitting, value-creating, profit-generating, systemizing, and commercializing approaches, based on the respective dimensions, preferences, and rationales (Huovinen 2013). The rationales are overviewed, the 13 high-degree, construction-related BM concepts are briefed, and the relevance is only qualitatively assessed approach by approach as follows.

3.1 Fitting business ideation and its relevance

Firms are crafting business ideas and accommodating *causal fit* concerning their offerings and operations versus targeted clients and needs. Applying Normann's (2001) abstract definition, a *business idea* is a unique, historically evolved set of factors related to each other, i.e., an environment with needs and values as well as a BU's offerings and other internal factors. The overall principle is one of consonance or fit. Adopting Drucker's (1994) recognized theory of business, the three sets of assumptions can be defined about (a) an environment, i.e. society, market, clients, and technologies, defining what a BU is paid for, (b) a specific mission, defining what meaningful results are and envisioning how a unit makes a difference in a targeted economy (society), and (c) core competencies, defining where a unit must excel to maintain leadership and accomplish its part of a firm's mission. Such a theory can be validated with the *four specifications*, i.e., the assumptions must fit reality, one another, be known and understood throughout a unit, and be tested constantly. There are the *two measures* for preventing the current theory from becoming obsolete, i.e., to abandon it and study non-customers. Readily, many fitting business ideation concepts have been designed as part of corporate planning concepts.

Among the 13 high-degree, construction-related BM concepts, the four concepts have been designed along the *fitting* business ideation dimension. Winch and Schneider's (1993) *four high-degree strategies* for UK architectural practices, based on the project complexity and the client's quality preference, capture many core *fitting* elements, i.e., (1) the strong, CAD-based delivery of designs with repeat elements for simple buildings at low fees and overheads, (2) strong experience and value engineering, coupled with many disciplines or specialization, to meet requirements related to complex buildings, charging a premium due to high value, (3) strong ideas and identifiable style with the articulation of a competence related to prestige buildings, coupled with charging a premium due to reputation for original, exciting ideas and a figurehead, and (4) strong ambition of young practices with few clients, and charging low fees.

Jennings and Betts' (1996) *high-degree four strategies* for quantity surveying practices in the UK capture many core *fitting* elements, i.e., (1) differentiation-based execution for small and medium-sized practices with a varied client base and simple, tailored, quality services to ensure repeat business, charging average fees, (2) differentiation-based expertise for larger practices with clients in niche markets and predominantly new areas, and complex, technically differentiated services, charging above average fees due to image of quality, adaptability, and professionalism, (3) cost focus-based efficiency for fairly new practices with simple, fixed projects, specific competences, optimized staff/salary levels, and rock-bottom prices, and (4) differentiation focus-based experience for larger, older practices with experience in complex projects and/or hand-holding services, and interpersonally bonded clients, charging a premium. Each strategy also identifies an IT-use level and a staff structure.

Lowendahl (2000) has designed the *three high-degree strategies* for US professional services firms with many *fitting* elements. (a) Client relation based strategies emphasize a unique ability to understand and help particular client groups. Performance is measured as client satisfaction, client retention, and follow-on contracts. Strategic assets involve senior professionals with reputation and client relationships. (b) Solution or output based strategies emphasize the exploitation of superior organizational competences. Vulnerability is related to solution obsolescence. When clients accept contracts without naming professionals, this is a sign of the successful development of collective routines and reputation. A challenge involves the motivation of R&D people to create new solutions to a large group of clients. (c) Problem solving or creativity based strategies result in highly complex firms typically delivering services based on innovations. Firms cannot avoid dependence on key individuals. Top managers are likely to be the best professionals who are willing and able to accept managerial responsibilities.

Helander and Möller's (2007) *high-degree, dynamic model for a system supplier's customer strategy* is based on the categorization of a client's strategies, with many core *fitting* elements, i.e., independence of supplier strategy A, shared expertise with supplier strategy B, and reliance on supplier expertise strategy C. A system supplier assumes (i) an equipment/material supplier role to causally couple with an independent customer's strategy A, (ii) a solution provider role to couple with a sharing client's strategy B, and (iii) a performance provider role to couple with a dependent client's strategy C. It seems that a supplier can extend its role only when a customer's strategy is compatible with the aimed role. A supplier's role may be dependent on interrelated activities and coordination mechanisms so that a client can close its knowledge gaps and start to perform activities that a supplier has performed in the past.

Thus, it is herein argued that in construction *Approach 1 is highly relevant*, at minimum, in the case of BU management aiming at causal fit between buyers and their needs, a BU's offerings to satisfy needs, and its operations enabled by key resources. Targeted professional clients couple needs with accommodating procurement methods whereas a particular BU achieves best fit between its solutions and such client investment and procurement behavior.

3.2 Value-creating business ideation and its relevance

Firms are crafting business ideas, specifying high-value propositions, and organizing BUs to actually produce values under contracts with clients and to capture shares of produced values. Applying Slater's (1997) founding client value-based strategy, market segments are selected, *value propositions* are created to establish positions of competitive advantage, necessary capabilities are developed for understanding client needs, and promised value is delivered. Relying on Ramirez' (1999) pioneering value co-production framework, BUs and clients could increasingly co-invent, combine, and reconcile values where interactions (offerings) are units of value creation and clients' roles are new factors of production. Applying Kothari and Lackner's (2006) typical value creation cycle, value is defined (sources and quantification), created, delivered for clients (flow and outside in -based processes), and captured (shares of profit, wallet and market). The value that clients receive from a focal BU's offerings is being determined by product, access, experience, and cost attributes.

Among the 13 high-degree, construction-related BM concepts, the five concepts have been designed along the *value-creating* business ideation dimension. Pinto et al.'s (2000) *high-degree value chain analysis*, based on partnering and a technique of client-based project success includes many core *value-creating* elements. A project supplier can redefine itself as a long-term partner for enhancing a client's competitive advantages and operations as well as eliminating disadvantages. Through value chain analyses, a supplier tailors project bidding, engineering, design, fabrication, and delivery in a manner and for a price that gives a client an advantage over using alternative methods or competitors. Client satisfaction is ensured through contract development, a client's multiple levels, and project-specific phases. In order to achieve an overall project success, a supplier enters cooperation with subcontractors to offer superior service to clients where technology is to a great extent undifferentiated.

Metais and Meschi's (2005) *high-degree, core competence-based strategy for strategic flexibility* via linking the value chain and resources of an (oil and gas) plant contractor involves many *value-creating* elements. A strategic architecture links a contractor's value chain and core competencies. There are four processes, i.e., (i) to understand market and invent new products, by analyzing products and services in cooperation with customers, (ii) to design generic solutions, (iii) to design and produce customer-specific solutions, and (iv) to operate solutions (constructed facilities). The five core competencies are project development, project execution, technologies, processes, and operation. This architecture enables to make choices between forms of a value chain and between types of competitive advantages. In unstable environments, core competencies allow for varying and adjusting a contractor's value chain, as a resource network, according to an industry's stakes.

Hawk's (2006) *five high-degree, most promising business ideas* for stakeholders in construction are as follows: (i) intelligent systems applications, (ii) lateral thinking capabilities, (iii) environmental concerns, (iv) decentralization needs, and (v) leisure time facilities. The *nine high-degree recommendations for international construction development* include many *value-creating* elements, i.e., (1) embrace consumer ideals, (2) seek new business ideas in cross-border customer relationships, (3) add new value potentials via innovative design and global procurement processes, (4) use of global construction to discover new local visions, (5) accommodate diversity while embracing the contradictory, (6) adapt and adopt cross-border design and production, (7) find and organize new knowledge across the globe, (8) innovatively avoid limits in hierarchies, and (9) integrate the Asian and European models of construction.

Salonen et al.'s (2006) *high-degree supplier centric systems model* for the enhancement of competitive advantages consists of the eight *value-creating* elements, i.e. (i) finding new ways to enhance customer value, (ii) adopting a supplier centric systems model with a shift to a systems integrator's role, (iii) identifying buyers who appreciate maximum value, (iv) insulating a systems integrator from threats via entry barriers, e.g., cost advantages, economies of scale, switching costs, unique and valuable resources, (v) acquiring and possessing required resources, e.g., superior systems know-how, systems oriented sales force, service capabilities, control of physical components, (vi) controlling costs, e.g., through standardization, (vii) integrating value propositions either as lowered total costs or enhanced performance for buyers throughout value chains and the life-cycles of systems, and (viii) communicating value to customers to change the predominant, buyer centric business model to the supplier centric one, e.g., signaling to gain top management's awareness and getting a mandate for containment of customers' line worker opposition as well as maintaining interfaces.

Kujala et al.'s (2010) *high-degree typology of the five empirical business models* of a power plant supplier also captures a *value-creating* scope. A 5-model framework was developed for the analysis of a project supplier's business models based on the six characteristics, i.e. customers, value propositions, competitive strategy, a position in a value network, an internal organization and capabilities as well as logic of revenue generation. The 1st model of basic installed base services involves product-oriented value propositions and transaction-based revenue generation logic. The 2nd model of customer support services involves process-oriented value propositions and transaction-based revenue generation logic. The 3rd model of operations and maintenance outsourcing involves product-oriented value propositions and relationship-based revenue generation logic. The 4th model of the delivery of life-cycle solutions involves process-oriented value propositions and relationship-based revenue generation logic. The 5th model of the development of life-cycle solutions involves process-oriented value propositions and relationship-based revenue generation logic accepting more risk and upfront costs as well as requiring more extensive business, market, and stakeholder management capabilities (in comparison with the 4th model).

Thus, it is herein argued that in construction *Approach 2 is highly relevant*, at minimum, in the case of BU management creating value by specifying high-value propositions, producing such value to clients, and a BU capturing its fair share of produced values. Farsighted clients look for markedly more or novel values for construction investments and, thus, a BU is collaborating with technology-intensive suppliers, proposing integrated offerings, and co-producing value.

3.3 Profit-generating business ideation and its relevance

Firms are crafting business ideas to achieve high-profit BU performance and also to sustain it. Adopting Slywotzky et al.'s (1999) multi-pattern approach to profitability, the rules of games can be redefined and *new profitable business designs* be recreated in terms of high client relevance, a consistent scope of products and value chain activities, a terrific profit model, a powerful source of differentiation and control across markets as well as a supportive, reinforcing organization. All this is enabled by the early, continuous recognition of evolving profit patterns such as mega, value chain, customer, channel, product, knowledge, and organization. The recognition, identification, and analysis of such patterns are based on paying attention to story-telling, mapping a strategic landscape, measuring degrees of mindshare by business designs as well as deciphering conditions and triggers for next profit-making patterns.

Among the 13 high-degree, construction-related BM concepts, only one concept has been designed along the *profit-generating* business ideation dimension. Leinberger's (1993) *high-degree dichotomy of project-oriented and process-oriented businesses* in US real estate markets captures many *profit-generating* elements, coupled with risk management. *Project-oriented business* exhibits five marketing characteristics (one project at a time, no guarantee of a next project, different projects, higher margins, higher risk), six financial characteristics (unique deal, changing financing markets for both equity and debt, project-by-project financing, huge financing needs, limited access to public equity market, and potential for surprises; restructuring of vehicles), and six organizational characteristics (job shop, barely contained anarchy, exciting and ever-changing, fighter pilots, high turnover, addicted to change). *Process-oriented business* exhibits differences in its five marketing characteristics (business stream, repeat business with satisfied customers, customer similarity, lower margins, and lower risk), six financial characteristics (uniform contract structure, consistent financing, corporate financing, working capital needs, broader access to public equity market, stable financing structure), and six organizational characteristics (assembly line, efficiently organized, consistent, ship's crew, stable workforce, slow adjustment when change occurs).

Thus, it is herein argued that in construction *Approach 3 is highly relevant*, at minimum, in the case of BU management focusing on generating profits, achieving high-profit performance levels, and sustaining them. Pioneering clients pursue complex investment aims that can be met only by radical solutions and, in turn, a BU is highly competent in innovating and proposing solution-driven values, realizing values, and capturing exceptionally big portions of them.

3.4 Systemizing business ideation and its relevance

Firms are crafting systemic business ideas as well as modeling or designing businesses and organizing businesses as systems. Applying Osterwalder and Pigneur's (2010) generative business model, rationales can be defined, i.e., how BUs create, deliver, and capture value as well as cover the four areas of a business (clients, offers, infrastructure, and viability). The 9-block logic of how to make money includes (i) client segments, (ii) value propositions, (iii) communication, distribution, and sales channels, (iv) client relationships, (v) revenue streams, (vi) resources, (vii) activity performance, (viii) partnerships for outsourcing and resource acquisitions, and (ix) a cost structure. *Business model innovations* result from the objectives, i.e., (a) to satisfy existing but unanswered needs, (b) to bring new technologies or offerings, (c) to improve, disrupt, or transform markets with better business models, or (d) to create markets.

Among the 13 high-degree, construction-related BM concepts, the three concepts have been designed along the *systemizing* business ideation dimension. Huovinen's (2003a) *high-degree, 5-element, knowledge-based system* for managing a firm's business units in global capital investment markets captures the core *systemic elements in knowledge-based ways*. (i) A unit advances front-line strategies and offerings for best solutions, high client satisfaction, and high firm profitability. Value-adding knowledge enables to pre-empt client needs. (ii) A unit integrates global, local, and contract-specific business processes for high dynamic operative effectiveness, ensured by virtual knowledge. (iii) A firm nurtures core technology for creating advantages. Innovative knowledge involves business-opportunity perceptions, a foresight, a technology platform, a core competence architecture, a core offering portfolio, and innovation paths. (iv) A firm governs and optimizes business-specific frames. This knowledge covers ownership, top management, venturing, financing, and firm-market interactions. (v) A firm extends its frame via collaboration with global and/or local parties. This knowledge includes synergistic ways of opportunity exploitation, benefit balance, and risk avoidance.

Huovinen's (2004) *high-degree, 5-element, organization-based system* for managing a firm's business in capital investment markets captures the *core systemic elements in organization-based ways*. The 1^{st} value-adding front line enables a BU to pre-empt client needs, excel among competitors, and meet its goals in the short term. A unit integrates the 2^{nd} business processes for ensuring virtual effectiveness. A firm nurtures the 3^{rd} back-end core technologies, competences, and offerings. Innovative organizing involves a core competence architecture and a matrix of core processes and project types where teams play flexible, integrative roles. A firm governs the 4^{th} BU frames. Framing solutions cover ownership, top management, venturing, financing, resource silos, and firm-market interactions. The 5^{th} extended frame includes collaborative ways of front-lining, process integration, competence fusion, benefit balance, and risk avoidance.

Huovinen's (2011) *high-degree, 5-element, high-sustainability system* for managing a firm's business in construction-related contexts captures the core *systemic* elements, i.e. a BU advances the 1st strategies and offerings also for the highest degrees of sustainability. Offerings with no/low negative impacts enable to pre-empt or over-satisfy client needs and meet high-sustainability goals in the short term. A unit integrates the 2nd business processes also for minimizing carbon footprints. A firm nurtures the 3rd back-end or core technologies also based on high-sustainability foresights. A firm governs the 4th frame of each business also for high sustainability. The 5th extended frame is also based on sustainability.

Thus, it is herein argued that in construction *Approach 4 is highly relevant*, at minimum, in the case of BU management systemizing or modeling its business around a core idea. Sectoral clients have large, multi-dimensional investment needs and, in turn, a BU is satisfying needs by engineering systems as wholes and delivering them as modularized parts.

3.5 Commercializing business ideation and its relevance

Firms are crafting business ideas and coupling them with new legal and organizational business entities, i.e., through entrepreneurship, innovation, business development, venturing, or spin-offing. Applying Looser and Schläpfer's (2001) traditional, 8-part business plan, business ideas can be identified and rolled out to start up high-growth businesses. Innovating may result in new products/services and/or business systems. Adopting Hamel and Breen's (2007) radical approach, management innovations alter managers' work or modify organizations and, thus, advance the goals of respective BUs. Principles, processes, and practices are being reinvented. A management innovation could have a unique capacity to create a long-term advantage when one or more of three conditions are met, i.e., (a) a novel management principle, (b) systemic with a range of processes and methods, and (c) a rapid-fire innovation. When higher tiers denote higher levels of value creation/defensibility in a hierarchy, the 4th tier of management innovations comes out above the 3rd tier of strategy innovations, the 2nd tier of product/service innovations, and the 1st tier of operational innovations.

None of the 13 high-degree BM concepts has been designed along the *commercializing* business ideation dimension. Nevertheless, it is argued that in construction *Approach 5 is highly relevant*, at minimum, in the case of BU management coupling its business ideas with intensively commercializing dimensions. Risk-taking clients with 'wicked' investment needs desire to enter high-innovation contracts and, thus, a BU is nurturing and using entrepreneurial competencies for the making of novel solutions and the realization of business cases profitably.

4. Conclusions

It seems that the business ideation dimension is being recognized among construction-related researchers, at least by the authors of the 13 high-degree BM concepts published between 1990 and 2013. Indicatively, the number of these high-degree concepts corresponding to one of Approaches 1-5 varies between zero and five (Table 2). Nevertheless, it is herein argued that each generic approach to business ideation is, at minimum, highly relevant in the case of BU management targeting preferred client investment and procurement behavior within construction markets.

Table 2: Correspondence between five generic approaches and 13 construction-related BM concepts designed to high degrees along the business ideation dimension.

Approach	*1 Fitting ideation No. (%)*	*2 Value-creating ideation No. (%)*	*3 Profit-generating ideation No. (%)*	*4 System-izing ideation No. (%)*	*5 Commerc-ializing ideation No. (%)*	*All high-degree BM concepts No. (%)*
No. of concepts	*4 (31)*	*5 (39)*	*1 (8)*	*3 (23)*	*0 (0)*	*13 (100)*

It is suggested that CIB-related scholars design next construction-related BM concepts along the business ideation dimension and adopt the most relevant approaches, respectively. Approach 1 calls for research on how to sustain fit between a business unit and professional clients when changes occur. Approach 2 calls for research on value co-production with farsighted clients, value capture, and offerings integration. Approach 3 calls for research on profit-generating mechanisms related to pioneering clients with complex investment needs and radical solutions. Approach 4 calls for research on systems related to sectoral clients, multi-dimensional investments, and system engineering. Approach 5 calls for research on entrepreneurial competencies related to risk-taking clients, wicked investment needs, and high-innovation contracts. Management in firms competing in construction markets are encouraged to assess the business case-sensitive relevance of each approach and try out those with initial high relevance.

Towards Responsive Workspaces - Identification of Service Paths for Time-and-Place Independent Work

Vitalija Petrulaitiene[1], Eelis Rytkönen[1] and Suvi Nenonen[2]

Abstract

The development of technologies, change in the ways of performing tasks and user preferences empower time-and-place independent work. Time-and-place independent work is becoming rather the rule than the exception. Half-empty offices and long traveling distances do not motivate employees anymore. Therefore, an attractive and welcoming work environment needs to be created. The definition of a workspace has evolved from strictly physical space to work towards virtual and social dimensions of knowledge creation. Virtual and social dimensions play an important role in a workplace due to digital revolution and empowerment of big data. Particularly, it helps to understand workers and their needs better and provide services that correspond demand which could then be called as a responsive workspace. A change towards responsive workspace becomes a challenge for real estate service providers as well. In order to gain competitive advantage, real estate service providers need to respond to the changes in the market. Therefore, this paper aims to analyse currently available services that support time-and-place independent work and identify key features and the course of service advancement that could help develop responsive workspaces. The aim is achieved by developing a service path framework. Literature review combined with market studies are used as methods for framework development. Literature review handles the trends of working environment and the market study consists of data of a hundred firms that offer services to support time-and-place independent work. As a result, key service paths are identified. Paths refer to a range of services, concepts and other solutions that support or contribute to time-and-place independent work. Four paths, characterized by space, community, technology and logistics as main business drivers, form the primary base of the framework. From this, new service paths that support different steps of knowledge creation processes emerged. Based on the framework, new business opportunities can be explored by real estate service providers. Further research can build on these findings by using other approaches, e.g. service design methodology or value co-creation theory.

Keywords: workspace, time-and-place independent work, services, framework

1. Introduction

New characteristics of the design and architecture of spaces and urban area, organisational transformations and changing ways of work need to be explored in order to support different needs of organisations. These rapid changes in the market and advancement of technologies challenge FM service providers to quickly respond to the developing needs and concentrate, above all, on supporting the worker. To understand the ways how time-and-place independent knowledge work can be supported, various services are analysed and paths are identified.

First, the paper discusses the theory related to knowledge processes and workplaces and identifies components of responsive workspace, then the role of FM service providers is shortly discussed. After the literature and theory review, the analysis of services is described and results are presented. The paper ends with discussion and conclusions related to the development of responsive workspace and the opportunities for FM service providers.

2. Literature

2.1 Knowledge creation

In today's quickly changing environment and technological advancements it becomes difficult to compete with anything other than the knowledge that an organization holds. Nonaka and Toyama (2003) discuss the knowledge theory of the organization to explain the process of knowledge creation and utilization. The knowledge creation is a process of interactions and problem solving happening between individuals, organization and environment. In many organizational theories, the environment outside the organization is ignored and its effects to knowledge creation are disregarded.

Nonaka (1991) tried to overcome this drawback and take environmental and organizational relationships into consideration by introducing the theory of SECI and studying interactions between them. In the knowledge creation theory, the knowledge is classified into tacit and explicit, where tacit knowledge is intangible and related to skills or points of view, while explicit knowledge is objective and rational, and is easily expressed with language and numbers (Senoo et al., 2007).

This classification lead to the development of SECI model for the knowledge creation process in four different conversion models: Socialization, Externalization, Combination, and Internalization. The process usually starts from converting new tacit knowledge through experience sharing and every day social interactions and is called Socialization process. Through the process of Externalization, the tacit knowledge is then transformed into explicit knowledge and gains tangible form such as documents or images. The personal knowledge and experiences are shared, and a person tries to find the meaning in these shared forms of knowledge. After the Externalization process and knowledge sharing with others, the knowledge is collected from different sources, combined, and processed into a more complex explicit knowledge through so called Combination process. In this step of the process, a lot of different tools are used and in many cases it involves virtual environment and virtual tools for knowledge creation and processing. When explicit knowledge is perceived and applied in everyday situations, it is transformed into tacit knowledge again, and benefits the knowledge of one's own. (Nonaka and Toyama, 2003).

Knowledge creation process is time, space, and relationship specific because it needs a place where information gets meaning through interpretation. This need leads to an introduction of "Ba" concept (Nonaka and Toyama, 2003). "Ba" originally means place and is considered a factor in a knowledge creation process that connects time, place and relationships with others (Senoo et al., 2007). Senoo et al. (2007) identified two "Ba" environments: physical (e.g. office) and virtual (e.g. email). However, Nenonen (2004) argues that there should be a combination of virtual, physical, and social places (e.g. mental space, ideas) as only virtual places cannot fully replace face-to-face interactions. These interactions are more important aspects in the knowledge creation process than the space itself (Huhtelin and Nenonen, 2015).

Organisations should aim at better understanding of complex knowledge creation process in order to increase their competitive advantage. Understanding employees and creating an environment that supports their needs should become a main priority of those organisations and their service providers.

2.2 Workplace

For a long period of time, workplace in the office was considered as a setting where employees followed orders (Senoo et al., 2007). In that setting, an office layout was appraised from a management perspective with staff left away from the decision-making process. Only later, starting from early 2000's, the workplace research showed the importance of Facility management (FM), IT and HR collaboration in order to improve collective activities and performance of employees.

In 2008, Vischer suggested that built environment is a necessity and it acts as a mediator between people and tasks and activities they perform. The better users are supported in their tasks, the greater is the effectiveness of the built environment they are in. Author divided users into three groups: individuals, the team, and the organization which was also related to the phenomenological perspective of space, which was considered in layers, starting from the "personal space" and moving towards universal space (Vischer, 2007b).

The understanding of "traditional" office space has changed when technological development created possibilities to carry out tasks in different places, including spaces outside traditional office walls. Data from different observational studies show that, on average, conventional workplace at the office is occupied 42-45% of the typical day (Laing, 2013). In his book "Work and the City" (2008), Duffy discussed traditional practices related to work time and work place. Nowadays, knowledge work is done not only through face-to-face collaboration in the office but also virtually. Virtual and remote teams also cause changes in work times as quite often team members are located in different time zones. Also, most of routine individual tasks can be automated and other highly intellectual tasks can be performed elsewhere and not necessarily in the traditional office building. These changes have an impact in how buildings and cities are used and how work can be combined with other activities.

Traditional office space became less about the employee interactions in a physical environment but more about individual's ability to work with digital information at the workstation and the role of a workplace has gained a different approach both in practice and in research. Nowadays, integration of various activities and possibility to be a part of various virtual and social networks that enable employees to create new knowledge are the most of important attributes of a good workplace (Lister, 2010).

2.3 Knowledge creation in workplace

New approaches towards workplace and its ability to support knowledge creation processes started in early 2000s. In 2004, Nenonen introduced the concept of four places that vary based on the type of work that is performed and space used to perform work (Fig. 1). Author argued that a Connective place is an external space where one needs to perform more intangible work (create tacit knowledge). Structural place includes external spaces where tangible work is performed and Formal place is internal environment where tangible work is done. The last place, used for knowledge creation, is internal, and intangible work is performed there. That place is called a Reflective place.

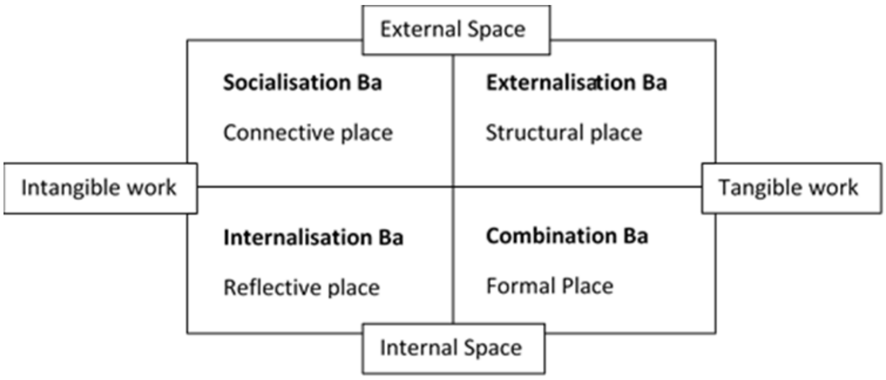

Figure 1: Work environments based on Ba concept (Adapted from Nenonen, 2004)

Huhtelin and Nenonen (2015) discussed the environment that supports knowledge creation and knowledge work. According to the authors, the aspects of spaces and services in Ba framework are:

- Spaces and services that support informal interaction and idea creation – Originating Ba;
- Spaces and services that support formal meetings – Dialoguing Ba;
- Digital platforms - Systemizing Ba;
- Spaces that support learning-by-doing - Exercising Ba.

Originating Ba is supported by spaces and services that support informal interaction – it needs to be a place where tacit knowledge can be transferred and co-created. Dialoguing Ba is supported by services and spaces that support formal interaction, and it is a matter of resources how to organize it as one function for empowering time-and-place independent work.

Table 1 introduces the generalization of discussed topics. According to Nenonen (2004), a workplace is combined of three components: physical space, virtual space, and social space. Thus, support services should be provided to all of those together to ensure smooth knowledge creation process and transition from one quadrant to another. Choo & de Alvarenga Neto (2010) introduced different steps in knowledge processes: knowledge creation, sharing/transfer and use of knowledge. These can be assigned to the three attributes of workplace. Different work types are also identified and categorized under three workplace environments.

Table 1: Ways of working, knowledge processes, and attributes of workplace in three workplace environments

	Physical Space	***Virtual Space***	***Social space***
Attribute of workplace	Place	Technology	Community
Knowledge process	Knowledge creation	Knowledge sharing	Knowledge use
Work types	Formal meetings	Virtual platforms	Informal interaction and idea sharing

2.4 The role of FM service provider

In order to understand the role of workplace and find new ways how to develop spaces that enable time-and-place independent work, two field of research should be analysed. Organizational theories claim that poor physical environment can have a negative impact on the performance but a good physical environment has little or no consequence to performance. Thus, a physical environment was considered as a hygiene factor in Maslow’s pyramid for many years and ignored by organization studies. Then, traditional facilities management (FM) theory divides FM services into three levels: (1) Strategic FM that supports organizations; (2) Tactical FM that supports business units; and (3) Operational FM – supporting end users, or in other words – knowledge work. FM’s role is to place the non-core business at the service of the core business in such a way that real estate would be turned from the cost item into the element that adds value to overall organisational performance. However, in practice, many organisations still consider real estate and workplaces as a hygiene factor and a cost item.

In order to change the understanding of FM as operations’ management, a philosophy was developed by Cairns. Cairns (2003) questioned the “irrelevance” of the physical environment and its placement in the Maslow’s pyramid. He claimed that a modern workplace is “not an activity container for paid work but contains representations of all other major social places in the modern society”. He explained that workplace must be seen as presenting different solutions to various physical and social problems simultaneously within the same assemblage of physical artefacts. This view is supported by Deb Roy (2015) who describes FM as something that: (i) delivers effective and responsive services; (ii) enables changes in the use of space in the future; (iii) makes assets cost effective; (iv) creates competitive advantage to organisation's core business; and (v) enhances organisation's culture and image..

Changes in the ways of working and the needs of employees and, thus, organisations, will affect how facilities are operated, maintained, and what services will be needed. FM service providers need to understand that effective and responsive services can be delivered only if they are flexible and adapt to the changing environment fast. For that, a good understanding of services that support workplace and work processes is needed.

3. Empirical part

3.1 Methodology

This study follows the steps of a qualitative approach in order to build hypotheses from the collected data (Eisenhardt, 1989). According to Yin (2003) a qualitative case study approach is suitable when the phenomenon and conditions are hard to divide and conditions relevant to the phenomenon need to be taken into consideration.

Extensive list of services were analysed with few service examples for an in-depth understanding as they enable creation of more robust theories grounded by diverse evidence (Eisenhard and Graebner, 2007). These services were analysed in multiple levels in order to get a better understanding of cases and the phenomenon related to those (Yin, 2003). The analysis of services was done by using Business Model Canvas tool, developed by A. Osterwalder (2004, 2010). Business model as a concept should be capable of reflecting how that vision can be converted into practice as it is between the strategic and operational layers. The understanding of a workplace covers three environments: physical, virtual, and social and knowledge processes are also divided into three steps: knowledge creation, sharing and usage. So data was analysed by taking into consideration these different aspects. Osterwalder (2004) provided a conceptualized tool to formalize the elements of business, relationships, vocabulary and semantics of a business model. This tool allowed to structure the business offering and logic into several levels with value proposition being the central topic for the approach

3.2 Analysis of data

During the process, 103 service businesses were analysed in total. Based on the Business Model Canvas tool, six key business dimensions were identified: value proposition, main user segment, revenue streams, resources, cost structure, and service providers for the first round of analysis.

After the initial analysis of services, the second round of analysis was conducted in order to identify the emerging patterns in the data. The revenue streams, resources and cost structure were not classified as these were not the focus of this research, so only main user segments, service providers and value propositions were sorted into categories. The main user segments were divided into three user personas which were constructed by using a story-telling approach and based on the time and the way the person works: 24/7 mover; 5-9 executor and 5/7 socializer. Then, the service providers and their value propositions were clustered into 3 main categories: Online platforms and Technology developers who provide technology (software, hardware, etc. e.g. Microsoft, Samsung), Spaces and Landlords – who provide physical infrastructure (e.g. letting spaces), and Places and Community operators – who operate and facilitate connections of people and organizations in either physical or virtual space (e.g. Facebook) and thus supporting knowledge sharing. After the initial clustering of services based on their value proposition, they were combined into four categories:

- Space: businesses and value propositions are mainly driven by real estate. It usually includes renting of premises for a fixed long period of time and is a square-meter based business for single organization or individual. For example, a BC (business centre) Papula can be put to this category;
- Community: businesses and value propositions are mainly driven by a community - likeminded people who have a common goal or want to share their thoughts in a certain theme. This category would include various events, conferences such as Nordic Business Forum, Slush, and others;
- Technology: businesses and value propositions are mainly driven by technology business like the development of a sophisticated software or hardware. Oculus, Built Environment Sensoring or other similar businesses can be put into this category;

Transportation: businesses and value propositions are mainly driven by logistical needs to transfer tangible things or people from one place to another. This category includes businesses such as DHL, VR, various taxi companies and others.

4. Results

After the second round of analysis and clustering of services based on their value propositions, the analysis on ways these services and businesses can support actual knowledge processes in the workplace was done. Results implied that the original four paths do not provide the needed answer, and new categories were emerging, mainly because of the technological development and the need to connect different resources from previous categories. Thus, the emerging new service groups were created based on the resources they are connecting and steps of knowledge processes they support or promote (Figure 2):

- Collaboration – services that support collaboration and businesses are driven by connecting physical space and community. Usually they include flexible contracts and shared spaces, co-working spaces such as Hub13, Kontoret and similar.

For example, mobile applications that allow users to know where people are, what they are doing, and who they are near, this way allowing serendipitous encounters.

- Sharing – services that enable knowledge sharing and businesses are driven by connecting community with technology. Community members participate in creating the content. E.g. LinkedIn, Airbnb, Lyft, Hoffice.

Organizations can create networks through different platforms such as LinkedIn or Facebook that allows organizations to understand how the inside community inside works. Such examples could be tags that are worn by employees to track their social behaviours online and within the organization, create possibilities to collect data and monitor team interactions and styles of communication.

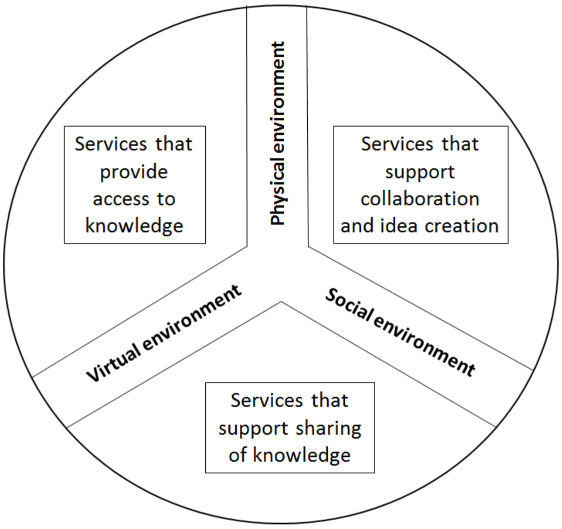

Figure 2: Services supporting work environments and knowledge processes

- Access – services that provide access to knowledge. Service providers create businesses by connecting physical spaces with technology or virtual platforms. E.g. Venuu, LiquidSpace, Foodora, MaaS.

Technologies that also connect people to the Internet of Things (IoT), facilitating marketplaces based on the intelligence of physical proximity.

5. Discussion

Identified service paths demonstrate an emerging trend of connecting multiple resources to provide value to the customer by supporting workplace, its user and knowledge creation processes. The value of new services is perceived through co-creation, in other words, by connecting different service providers and users in service design and value proposition.

The concept of value co-creation was first introduced in theory of service – dominant (S-D) logic, presented by Vargo and Lusch (2004). Value co-creation has been adopted as a core concept for the development of service system science and relates to innovations and collaborative consumption. New emerging services, which were analysed in this research, employ value co-creation and, thus, reflect innovations. Furthermore, changing workplaces indicate collaborative consumption approach. Previous case studies suggest that the future of the workplace will change not only in terms of how and where work is accomplished but also in terms of how the workplace is consumed by its users. For example, a growing relevance of collaborative consumption provides possibilities for users to choose from a wider pool of options and gain greater control of their work environments by using workplaces on as-needed basis in desired location or environment. A good example of these types of collaborations could be WeWork spaces and their Shared resources in USA. The network of small businesses benefits from shared resources such as healthcare plans, car rental memberships, offices amenities, and others.

As stated earlier in the paper, the workplace consists of 3 components: physical space, virtual space and social space. The workplace enables three processes related to knowledge: the creation of knowledge, knowledge sharing and the use of knowledge (Choo & de Alvarenga Neto, 2010). Therefore, FM services for supporting workplace need to take into consideration all three components and three processes - services for informal interactions, formal meetings, and also services that support virtual work. However, analysed services and businesses are mainly connecting two out of the three workplace components and one or two knowledge processes: either supporting knowledge creation, knowledge sharing, or improving the ways of using of the knowledge.

5.1 Limitations

FM services outside traditional categories are researched scarcely. Previous studies concentrated on services provided for organisations and their none-core activities. In parallel, another approach to services supporting knowledge exchange within and beyond organisation has emerged. Therefore, more studies regarding knowledge processes and workplaces that involve premises other than organisational offices are needed to support tentative findings.

The selection of the analysed services might be questioned as a qualitative approach and, also, the inductive research require careful selection of cases in order to avoid informant bias and present empirical richness. Also, according to Yin (2003), returning to the global issues after the analysis of individual units might be challenging.

The clustering of services can be argued as no users and service providers were interviewed, it was intuitive and based mainly on expertize of multiple researchers that were involved in the data gathering and analysis. The usage of Business Model Canvas tool can also be questioned as it is not widely used in research environment.

6. Conclusions

The results of this analysis indicate that FM practitioners should concentrate on offering work environment that supports various knowledge creation processes. It is not enough to provide technological solutions, space, and services related to social environment separately, but collaboration between service providers is necessary. In practice, it might require much closer collaboration and partnerships within organisation’s departments as well as working together with outsourced services’ providers. For FM service providers outside organisations, this increased collaboration and supporting knowledge processes means that they need to change own business strategies and try to understand processes of end users, in other words, employees of organisations, to be able to offer services that meet their needs the best.

Technology is increasing the value of physical places by facilitating both physical and virtual networks together rather than replacing the physical place as it is. So the logic of using technology and combining it with the new ways of working is that new kind of workplaces can be shared, used more intensively, in various ways and on-the-need basis. In order to respond to knowledge workers' demands and improve communication processes through simultaneous transformation of all workplace environments, FM should provide flexible services, and offer various co-working and workplace on as-needed basis models. Workplaces should provide all needed services and be designed in such an environment what would create possibilities for and facilitate various social, intellectual, commercial and other types interactions within and between organisations.

Further research could include a comprehensive analysis of knowledge creation processes and changing ways of working inside organisations could help in identifying service opportunities for real estate service providers. Also, the services under identified categories could be explored in more detail in order to understand how real estate service providers' business strategies should change.

Abstract

This paper examines water cooperatives in Finland and Denmark, and in particular it delves into the future of water cooperatives. During recent years, the trend has been that big is beautiful -- larger organisations can achieve economies of scale. Is there still a role for water cooperatives in the future? Both in Finland and Denmark cooperatives have played, in particular in rural areas, an important role in the development of economic activities and improvement of living conditions. Water cooperatives are still very common. More than 40% of the Danish population is supplied water by a total of 2,500 water cooperatives; Finland has roughly the same number of water cooperatives. In both countries municipalities are, in principle, responsible for the provision of water services for the inhabitants. In Denmark cooperatives have a strong status in legislation as water service providers outside large population centres. Finland is a sparsely populated country with large rural areas between built-up areas. Municipal water utilities cannot afford to extent their networks in rural areas. Development of improved water services has been left to the residents and cooperatives have proved to be a workable solution.

Keywords: water, cooperatives, Finland, Denmark

1. Introduction

Finland has a long tradition of water cooperatives, which presently number over 1,500, and supply water to 13% of the population, mainly in rural areas (Luukkonen 2013). Larger towns and cities are typically supplied by public water utilities. Water cooperatives in Finland are quite different from each other even though their basic task – to produce water and often also wastewater services – is similar. The Finnish water sector has a lot in common with that of our neighbour Sweden, except for water cooperatives. Sweden has hardly any water cooperatives, and the same applies to Norway, too.

On the other hand, in another Nordic country Nordic country, Denmark, water cooperatives play an even bigger role than in Finland. More than 40% of the Danish population is supplied water by a total of 2,500 water cooperatives. Contrary to Finland, cooperatives in Denmark have no role in wastewater management which is by legislation the responsibility of the municipalities. At the beginning of the 20th century, virtually all the needs of rural communities were met by cooperatives (Birchall 2004). In farm product processing and distribution cooperatives still play a major role. Dairy cooperatives, for example, hold a market share of 97% (DGRV 2015). A newer development has been windmill cooperatives, which were established in particular during the 1980s and the 1990s so that at the turn of the century 80% of the windmills were owned by cooperatives. This trend has changed in more recent years as more utility-size wind projects have come online. (Cook & Lin 2015)

Elsewhere in Europe water cooperatives exist e.g. in Austria, Germany and Italy. In Austria, cooperatives cover 12% of water services being important for sparsely populated areas (Bauby 2012). Cooperatives have operated as regional energy utilities in many parts of Germany for well over 100 years. Over the last three decades more than 800 new cooperatives have been founded in the field of renewable energies in Germany (DGRV 2015). In the USA, cooperatives are the most common organizational form of water provision in suburban and rural communities and totally there are about 3,300 water cooperatives (ILO 2015).

Water cooperatives are private utilities. They are established, owned and managed by the people who are also the beneficiaries of their services. One basic principle of cooperatives is that members have equal voting rights, which means that an outsider cannot become an owner and thereby a decision-maker in the cooperative.

Cooperatives resemble private companies in that they need to cover their costs with the income they generate. But, according to cooperative principles, there is no need to generate profit to be distributed to the owners. Any profit is used to improve the system and the quality of services. Cooperatives operate on the 'full cost coverage' principle. Thus their tariffs reflect the real cost of the service provided. In many countries the activities of municipal water utilities, on the other hand, are subsidised by the state or local authorities.

This paper examines water cooperatives in Finland and Denmark, and in particular, the future of water cooperatives. In recent years, the trend has been “big is beautiful” – larger organisations can achieve economies of scale. Is there still a role for water cooperatives in the future?

2. Water cooperatives in Finland

Water cooperatives in Finland differ dramatically according to their physical environment, settlement pattern, acute needs of the population, and the legislation in force at the time of establishment. They can be classified into the following five groups (Takala et al. 2011, Pietilä 2015):

1) Water cooperatives established prior to 1950 in rural areas
2) Water cooperatives established in rural areas in the 1950s through the 1970s
3) Water cooperatives established in rural areas during the 1980s and 1990s
4) Water and wastewater cooperatives established since the 2000s.
5) Water cooperatives for rural townships established mainly in the 1950s

Only a few cooperatives of the first group provided sewerage services since wastewater was at the time discharged mainly into the septic tanks of individual properties. These cooperatives were established and operated solely by their members, as municipalities or the state did not have any support mechanisms in place (Juhola 1990). Wooden pipes were widely used and pipe laying and related work were mostly carried out by the members themselves. The initiators of the cooperatives were those whose demand for water was most urgent, such as dairy farmers. Since the 1950s the structure of the Finnish farming sector has changed dramatically: the number of dairy farms is now a fraction of what it used to be, but water cooperatives still exist.

The second group of water cooperatives was established when Finland was slowly recovering from World War II – since 1951 it was possible to apply for a subsidy or loan from the state to construct water or sewerage systems in rural areas. During the early years these subsidies were marginal and had hardly any impact on the economy of the cooperatives. As state authorities supervised all projects funded by state subsidies or loans, the resulting improved workmanship had a much bigger impact. Municipalities were not entitled to these support measures, only rural systems.

The third group of water cooperatives was established as some municipalities decided to extend their water supply and wastewater systems to rural areas in order to provide safe and reliable services to a larger share of their population. Several municipalities supported cooperatives by giving technical assistance in planning and construction, by subsidies, or by guaranteeing cooperatives' bank loans. For instance, the municipality of Pudasjärvi has 40 cooperatives, most established in the 1980s (Pietilä 2015). After Finland joined the EU in 1995, it has also been possible to get subsidies for cooperatives via some EU funding mechanisms.

The fourth group came into being after 2000 to supply water and increasingly also wastewater services in rural areas. People have become more aware and require higher quality drinking water. The water of their own private wells does not necessarily meet their requirements. On the other hand, people have also moved to rural areas thereby increasing population density there, which makes centralised water supply and sewerage a more viable solution. People moving from towns and cities are used to centralised services and ere are not interested in having and operating their own individual water supply or sewerage systems.

In 2004, legislation concerning wastewater disposal requirements for properties not connected to centralised sewerage (with their own disposal system) was tightened radically. As a consequence, most of the water cooperatives established since then also provide sewerage services. In addition, many previously water-only cooperatives have also built sewer systems. It is typical of cooperatives established in the 2000s not to have their own water intake or wastewater treatment facility. They buy water from a larger entity, typically a municipal water utility, and discharge wastewater to a municipality's sewer network. Only a few cooperatives have built their own water intake or wastewater treatment plant in the 2000s. The shift from owning a water intake to buying water from another utility started earlier as can be seen from Table 1.

Table 1. Water sources of private water utilities[1)] in South-West Finland (Ryynänen 2003)

Established	*Own water intake*	*Water bought from another utility*	*Total*
- 1949	*11*	*0*	*11*
1950 - 1959	*19*	*0*	*19*
1960 - 1969	*20*	*2*	*22*
1970 - 1979	*25*	*29*	*54*
1980 - 1989	*16*	*11*	*27*
1990 - 2002	*7*	*64*	*71*
Total	*98*	*106*	*204*

1) In addition to cooperatives, this table also includes small informal units and companies

The fifth group of cooperatives was established at a time when few rural towns had a centralised water and sewer system – residents relied on their own wells and septic tanks. Over the years, these cooperatives have expanded and presently cover not only the township but also the surrounding rural areas so that coverage can be up to 99% of the population of the entire municipality. Many of these cooperatives have from the beginning also provided sewerage and wastewater treatment, while some originally established for water supply only have later expanded their activities to cover wastewater services as well. (Vihanta 2013)

3. Water cooperatives in Denmark

In Denmark water cooperatives have had, and will have also in the future, an important role in the provision of water services to the citizens. Typically in cities and larger towns water is supplied by municipal water utilities, but in smaller towns and in rural areas water is supplied by private water undertakings, which are mainly cooperatives. As municipal water utilities are typically large, their number is only somewhat over 100 while there are about 2,500 water cooperatives. The size of these cooperatives varies from 10 to 20,000 households, while on average one cooperative serves 400-600 households. The number of cooperatives has during the recent decades gradually decreased via mergers, as in 1990 there were still more than 3,000 of them. Water supply is very decentralised in Denmark. In addition to cooperatives, there are some 50,000 households not connected to centralised supply that use their own private well. (GEUS 2015, Sørensen 2010)

In Denmark, the source of water is almost entirely groundwater and normally the quality of the water is good enough for drinking water requirements. In fact it is not allowed to treat drinking water using chemicals. Water is chlorinated only in exceptional circumstances. By area, Denmark is a rather small country (42,900 km^2), with a relatively big population density of 130 inhabitants/km^2, compared with only 16 inhabitants/km^2 in Finland. Extensive farming in Denmark in the vicinity of wells and boreholes has resulted in groundwater contamination in particular in the form of excessive concentrations of nitrogen and pesticides. As a result, annually tens of water supplies have been closed during the last decades. This problem has been tackled in recent years by tighter regulation on the use of fertilizers and pesticides. (GEUS 2015)

Danish water cooperatives have established a joint organisation, Danske Vandværker

(Association of Waterworks in Denmark), to assist and support its members. This association has a staff of about 15 experts who can help the cooperatives in various technical, financial, legal etc. questions. The organisation has also produced tailor-made guides and manuals, and it has arranged education and training events. Danske Vandværker has also negotiated an attractive insurance policy for its member cooperatives. (Danske Vandværker 2016)

4. Strengths and weaknesses of water cooperatives

Cooperatives fit very well into the EU's subsidiarity principle – decision-making at the lowest appropriate level. In Finland, at least in political discussion and decision making, the trend in the recent years has been the opposite – big is beautiful and more economical. That may be true in other sectors, but not necessarily in water services, which are by nature local activities. Merging of large networks in rural areas does not automatically provide the economic benefits of larger units. The relative effectiveness of large water utilities in cities derives more from high population density than the utilities' high productivity. Also in Denmark the trend has been towards lager units. A thorough municipal administration reform was carried out in 2000, when the number of municipalities was reduced from 271 to 98. Consolidation of water sector has also been discussed (Sørensen 2010).

Operation of small cooperatives is typically voluntary work. People are often willing to do voluntary work in their own neighbourhood or at the village level, but if a cooperative covers several villages, people no longer consider it their own and are less motivated to work without compensation. In Denmark the strengths brought up in connection with cooperatives include: a) dialogue and political contacts with many stakeholders through a widespread network, b) large public support, and c) direct contact to local authorities. Possible weakness may be a financially weak starting point but this can be overcome by cooperation with municipalities, utilities and investors. (Danmarks vindmølleforening 2009). In Finland, municipalities have often co-financed the investment costs of water cooperatives with up to 25% and also guaranteed cooperatives' bank loans (Pietilä 2015).

It is true that many water cooperatives are small, and they often lack sector technical or economic skills and knowledge. But, on the other hand, their systems are also often very simple thus requiring much less expertise compared to the utilities of towns and cities. In Finland, the majority of small water cooperatives do not have their own water intake but buy water from a municipal water utility. Similarly, only a few cooperatives run their own wastewater treatment plant but discharge wastewaters into a municipal utility's network. Thus they only have to take care of their own wastewater networks. In Denmark, water supply is almost entirely based on the use of groundwater and water cooperatives draw water from their own wells or boreholes.

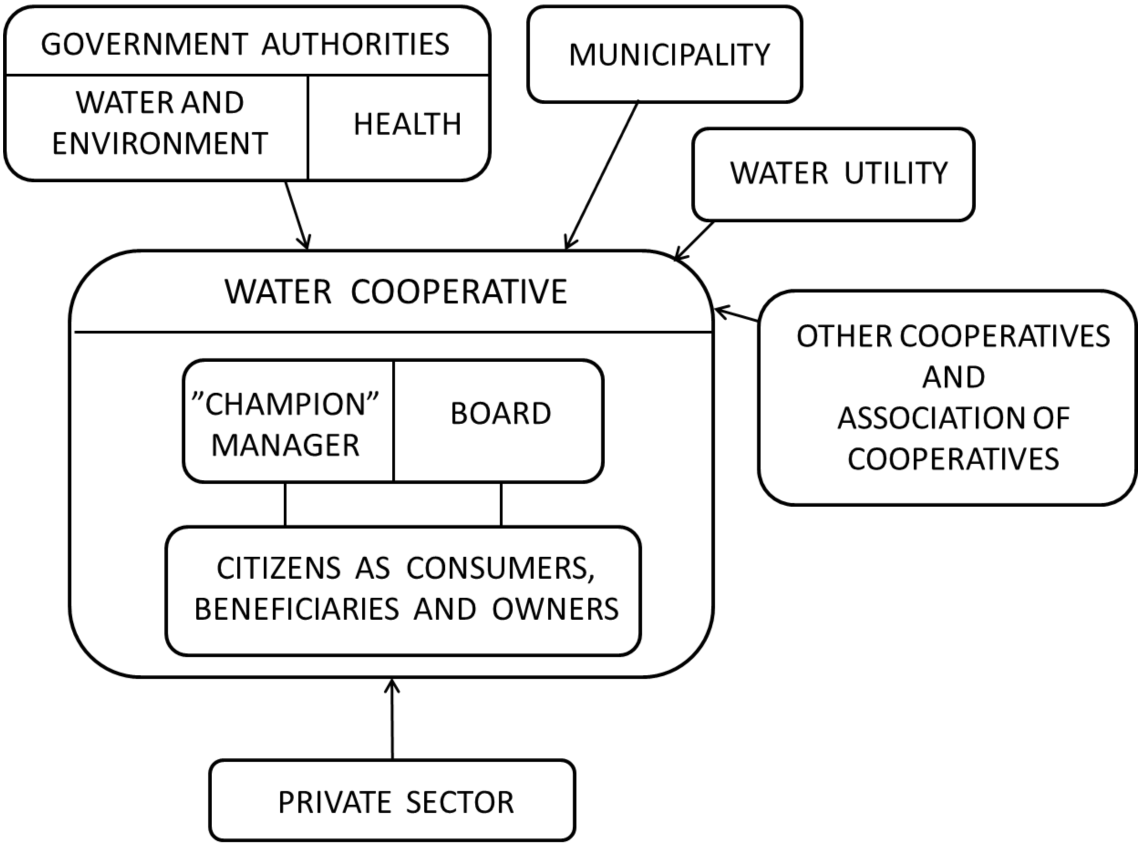

Figure 1. Water cooperatives and various stakeholders

At least in Finland, members of water cooperatives are often quite passive as long as everything goes well, and do not attend official meetings. But the meetings can be crowded and very intense, for example, if there is a need to increase tariffs substantially, or if someone tries to take over the water cooperative against the will of the people.

Many water cooperatives, in particular smaller ones, are facing difficulties. The active members are getting old, and it has proven difficult to get the younger generations involved in voluntary work. All those involved need to increase their knowledge and improve their skills. Undocumented tacit knowledge can also be a problem. Only the older employees of the cooperative who constructed the pipe network know its exact location. When these people retire, locating the networks will require much effort. Cooperatives could buy and utilise certain expert services, but as the members are used to cheap tariffs, higher charges are resisted. On the other hand, as there has not been much demand for expert services suitable for water cooperatives, only a few service providers exist at least in Finland. The situation is gradually improving as cooperatives are slowly becoming more trusting of external expert services, or they just have to use them when none of the members of the cooperative is willing to be in charge of the activities.

Closer cooperation between water cooperatives may ease some of the problems small cooperatives are facing. In Denmark the cooperatives are well organised as they have established their own support organisation, Danske Vandværker. In Finland a similar organisation called SVOSK (Association of Finnish Water Cooperatives) was established in 2009, but so far the resources and activities of SVOSK have been rather modest in comparison with its Danish counterpart. SVOSK has organised annual national water cooperative workshops and training events with various partners. In the Kouvola Region, in South-East Finland, some 30 local water cooperatives established a joint association to support their activities. Similar regional associations are also planned elsewhere. (Pietilä 2015)

In Finland larger water cooperatives (the fifth group) are in a much better situation. They are large enough to employ enough staff to run their operations. In comparison to municipal utilities of the same size, these cooperatives have a clear operating principle – to produce good quality services to members with funds collected through charges. Municipal utilities are subject to political control which often makes long-term planning difficult. The goal of politicians is too often success in the upcoming elections, not necessarily the long-term good of the community.

The benefits and problems of water cooperatives are summarised in the SWOT-analysis below (Vihanta 2013, Pietilä 2015).

Table 2. SVOT analysis of water cooperatives

<u>*Strengths*</u>	<u>*Possibilities*</u>
- *flexible decision-making*	- *official status in municipality's water service structure*
- *decisions normally made without voting*	- *residents no longer need to take care of their individual systems*
- *no political motives in decision-making*	- *cooperation and quality of joint activities can be improved and less need for voluntary work*
- *creates solidarity*	
- *clear operating principle: expenses are covered by charges*	
- *municipal boundary does not restrict activities*	
<u>*Weaknesses*</u>	<u>*Threats*</u>
- *reliance on one person*	- *members get tired of voluntary work*
- *lack of skills*	- *not enough voluntary activists*
- *members get passive after system is operational*	- *in a small unit personal relations may get strained*
- *one or a few active persons may direct activities in an unwanted direction*	- *authorities' requirements become unnecessarily strict*

5. Role of water cooperatives in the future

Water cooperatives will remain important water and wastewater service producers in rural areas in Finland. Municipal water utilities will not be able to cover the rural areas to the extent that cooperatives have been able to. In Denmark cooperatives have a much stronger status as they are defined in the legislation as preferred water supply organisations in rural areas. The number of water cooperatives in both countries is expected to decrease as small cooperatives merge with each other or into a municipal utility.

The majority of water cooperatives are small and largely managed on a voluntary basis. It is useful to have support systems for these small cooperatives so that their operation and management practices reach a more permanent and professional level. In Denmark, this is already quite well organised via Danske Vandværker, but in Finland only the first steps have been made. Cooperation between cooperatives should also be encouraged.

There are a number of larger water cooperatives which operate as professionally as municipal utilities of the same size. Such cooperatives can be expected to remain independent water and wastewater service producers. In a number of municipalities in Finland a cooperative takes care only of water supply and distribution while the municipality is responsible for wastewater services. Some municipalities would like to transfer the responsibility for wastewater treatment to the local water cooperative.

In principle, Finnish water services are not affected by the financial situation of the municipalities since, according to the law, all costs related to water and wastewater service production should be covered by water charges. The charges should be sufficient to also cover maintenance and investment costs in the long term. In the case of municipal water utilities this principle does not always apply. In many municipalities the profit earned by the water utility is used to support other municipal sectors. That is not bad in itself – the money benefits the municipality's residents. Nevertheless, if the water utility is left with too little to spend on renovation and rehabilitation, the future of water services is threatened. With water cooperatives the equation is simple, as all costs are covered by charges, and any profits are used to improve the service.

6. Conclusions

According to the Finnish legislation, municipalities are responsible for water and wastewater services within their areas. Yet, a number of municipalities have no water or wastewater utility but a cooperative provides these services for their residents. In some such municipalities water distribution coverage is up to 99%, which is well over the national average of just over 90%. Several municipalities are currently discussing their sewerage management with the local water cooperative. They would like to transfer the responsibility for the sewerage system to the cooperative.

In Denmark cooperatives have a well-established role in water supply outside large population centres. Wastewater management is by legislation the responsibility of the municipalities. This is different from Finland, where cooperatives often take care of wastewater as well.

The ultimate goal of water and wastewater cooperatives is straightforward: to produce good quality service to their members and cover related costs by the income they generate. As cooperatives are not under municipal administration, they are not subject to political decision-making. On the other hand, as they do not have to earn a profit for their shareholders, no external price regulation is necessary. Cooperatives are well in line with the commonly agreed principle of subsidiarity which suggests that decisions should be made as close to the affected people as possible.

Ageing infrastructure is a common problem in European countries. The renewal rate of the water and wastewater infrastructure of many Finnish utilities is unacceptably low. At the current rate of renewal, the pipelines would have to serve for 200 years, which is simply impossible. In Denmark, too, pipeline renewal rate of municipal water utilities is not sufficient. On the other hand, many water cooperatives have been able to maintain their networks and renew ageing pipelines in due course. Yet, the water tariffs of these water cooperatives can be lower than those of municipal utilities of the same size. Our findings suggest that the cooperative is a more efficient management organisation than a municipal utility, but further research is needed to confirm that.

The public sector in many European countries will face serious financial challenges in the future. People will live longer than before, which is going to increase pension, health care and other social security expenses. At the same time, the share of the working age population will decrease. Consequently, at least in Finland and Denmark, the current welfare state can no longer be sustained on public funding alone. New ways of providing public services must be found. Cooperatives are a successful example in the water sector.

Abstract

Measuring productivity for accurate forecasting in construction scheduling is one of the most important problems that managers face nowadays. The traditional measurement methodologies are obsolete and offer deficits in (measurements of) standardization, which causes inaccurate assumptions during the planning phase of a project, affecting the predictability during its execution. With the aim to contribute to the solution of this issue, a new methodology for information acquisition under cloud computing and storage was developed to provide the necessary tools for collecting, measuring, and reporting the production work in order to compare the results between different projects and subcontractors. The objective of this paper is to introduce how the tool was obtained, the process of its creation and the benefits obtained from its implementation. This approach enables the manager to notice the progress of each of the projects, compare them with each other, and make decisions to improve processes; thus, increasing productivity and reducing variability. In addition, this tool provides a starting point to apply advanced forecasting techniques for more accurate predictions in real, and complex environments under volatile conditions. This paper fits into the category of "Advancing Products and Services" because it describes a program that innovates the production control work.

Keywords: Construction industry, productivity, technology in construction, forecasting in construction.

1. Introduction

Average annual growth of Colombian construction over the last five years is 16.8%, compared to the rest of Latin America and the Caribbean, with an average annual growth of 10.2%. This makes the Colombian construction industry the third largest in the region (data from the Ministry of Commerce, Industry and Tourism, 2013). Despite the elevated operative costs and low productivity yielded by traditional construction methods, project revenue has been considerably high in the past. Nevertheless, competition in the industry has greatly increased over the last few years, which has pushed constructors to restructure construction methods in order to improve productivity to be more competitive in the market.

Measuring production rates in construction plays a crucial role when it comes to improve on-site productivity as these rates are indispensable for the controlling and planning of civil projects. According to a study on productivity rates by the International Labour Office (ILO):

> *The critical figure is the productivity norm. (...) If the task is underestimated by 30 per cent, (..., the direct cost of the project will increase by 30 per cent. Conversely, if the tasks are overestimated, then much of the workforce will not be able to meet its targets and there will be considerable disruption and discontent on site.*
> *Estimating the correct productivity is probably the most important decision for the engineer (ILO, Stield, Brudefords & Shone, 2003).1*

Thus, the importance of developing an efficient method allowing for data collection and analysis of construction productivity is highlighted, with the aim of facilitating the accurate decision making, in order to help improve construction productivity.

Current production rates measurement in Colombia is not standardized or effective. This gives way to sizable issues in planning activities and decision making. In most cases, measurement formats are confusing and inefficient, which fosters the input of incorrect information. Not being comfortable with the structure of the format, the operators in charge fail to put enough effort in filling it out correctly. Moreover, performance measurement is not among the functions of any operative position. Therefore, this task is sometimes accomplished by the Lean engineer, sometimes by the administrative engineer, the foreman or foremen in charge, or is even neglected altogether on occasion. In sum, this absence of staff charged with measuring activity productivity, along with lack of clarity in the formats, makes for low reliability in performance control, thus affecting future construction work and accurate decision making aimed at improving productivity.

Considering the foregoing, a Decision Support System (DDS) was designed, consisting of an application allowing for the measurement of productivity in a friendly, intuitive and efficient fashion. In the same manner, it processes the information and generates reports that can be used to make accurate decisions, thus improving the efficiency of the processes and of the on-site activities.

The main objective of this work was to create a largely useful product for any construction company. For this reason, the development process for the model was based upon the methodologies found in the book The Lean Startup by Eric Ries (2011). The book touches upon the importance of carrying out an iterative process involving the final user, in order to develop a high quality product while investing the least amount of resources possible.

2. State of the art

[1] Taken from http://www.ilo.org/public/english/employment/recon/eiip/download/prod_norms.pdf, Page 7.

Measuring productivity in the construction industry has acquired meaningful importance over the last few decades (Rivas et al. 2011). Nevertheless, Colombia has seen little advance in this topic due to the large revenues left by the industry in past years.

Nowadays, measurement of productivity does not happen for most projects, as it is a dispendious activity. In general, the 5 Minute Test (Koskela, 1992) lean tool is applied instead of measuring the daily progress of a given activity. This Test includes measuring staff performance in a given activity for five minutes, which allows reducing time wastage by optimizing space and processes. However, this is not a tool that allows checking an activity's daily progress. Numerous studies have been conducted on the topic of productivity since the 1960s to this day, largely owing to growing market competition and the need of companies to increase their revenue. Chart 1 shows the percentage of articles published on academic journals since the 1980s. The chart shows that interest for improving productivity is still quite relevant in the construction industry.

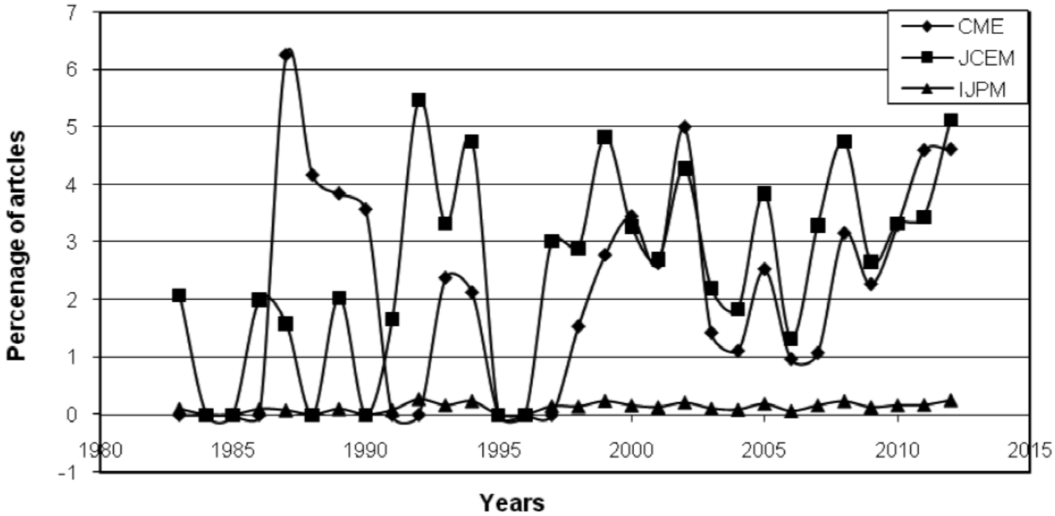

Chart 1: Article Production on Productivity in Construction. Dolage D.A.R. et al. (2013) [Graph]. Progression of Productivity Articles in Journals. Taken from Productivity in Construction – A Critical Review of Research.

In 1965, the United Nations conducted a study on factors affecting on-site productivity, focusing on repetitive processes in construction operations (Enshassi et al. 2014). In 1974, NECA conducted a study on the influence of different climatic factors on workforce productivity (Rivas et al. 2011). Some authors have looked at the topic from other perspectives. For instance, in 1986 Borcherding, Palmeter and Jansma studied unproductive times affecting the efficiency of construction work. Other authors examined the topic in 1997 and 2005, using advanced statistical models and software programmers to determine the variables affecting productivity, as they considered such variables to be too complex for the human brain to process (Dolage & Chan, 2013).

Despite great efforts to improve productivity, Colombia continues to have problems measuring it properly. Construction companies lack standardized methods to collect and process the information, let along consider determining the factors affecting productivity.

2.1. Methodology

The project was developed in three stages, namely: initial analysis of the current situation, proposal of the DDS, and development of the application. These stages shall be described from here on.

2.2. Initial Analysis

The first step in determining the problems to measure production rates was visiting construction sites to observe how the data was collected. The main issues observed in the processing and analysis of production data are as follows:

a. Problems with the construction companies in taking, processing and interpreting the site productivity data. This issue is evidenced in the following aspects:
    1. Lack of item standardization, along with duplicate activities.
    2. Excessive or lacking specificity. Usually, activities are not sufficiently differentiated according to the characteristics directly affecting its productivity (e.g. vertical or horizontal veneers). There are also instances of excessive specificity, differentiating activities by completely irrelevant characteristics (e.g. distinguishing between a 30x30 red horizontal veneer and a 30x30 white horizontal veneer).
    3. Difficulty of standardization activity measuring units, or lack thereof.
    4. Lack of clarity about who is charged with measuring production (DT – Data Taker). Sometimes, data collection is too dispendious, and is therefore neglected.
    5. Though there are adequate formats for data collection and analysis, the DT does not use them properly. This leads to incorrect or incomplete data input, which clutters the reports and makes proper data analysis impossible.

b. Lack of reliability in the results due to the absence of a representative sample. By failing to continuously following up on activity productivity, there is not enough data to have a statistically representative sample, leading to biased reports.

c. Activities are only measured once a day. If only one measurement is available for one given activity, the subsequent reports will reflect that the activity does not vary, that is, that production is constant in time. Construction is a complex system, affected by multiple factors. For this, to state that production is constant and unchanging is unlikely.

d. The reports generated are not easily understood or interpreted.

e. Lack of initiative from the staff involved in proposing measures to improve the internal handling of data collected on-site. Oftentimes, a passable information collection and processing format exists, and no effort is made to improve it.

f. Lack of human and material resource allocation for the development of real follow up and control on project progress.

g. In view of the foregoing problems, the need to devise a system to solve them became evident: the creation of a DDS for the collection, measurement, reporting and forecasting of data productivity rates.

3. Proposal of a DDS for Productivity in Construction

The initial proposal presented to the company contemplated the improvement of the quantification of production units, aimed at bettering estimate reliability. Thus, the purpose was for the amounts to be updated using the amounts obtained in a construction site to design a database with production rates. The objective was to build a relational, parametric database per work unit and project type. To that end, a strategy was defined in order to collect information and feed the database.

At first, the construction company requested the database to be built in Excel. However, doing so in a web server yielded better results, as it allowed for better data processing (greater speed and ease of handling). After submitting these observations, the company agreed. Moreover, the company requested for a strategy sustainable in time to allow anyone to develop this methodology.

Three options for the collection of data were analyzed: the creation of a simple printed format for the use of foremen on-site or, in special cases, of the operator executing the activity to fill out unsupervised;

the creation of an Excel sheet to be accessed from a tablet or smartphone allowing for data input as the site is reviewed; and finally, the design of a web page allowing for data input or, in the event that internet access is not available, for the printing of the format. After studying all three alternatives with the company, the third proposal was selected. Hence, a user-friendly web page was created, that accomplished the efficient collection of production rates on-site, and that also considered the factors affecting the selected type of productivity, in order to conduct a future study about said factors.

To guarantee product quality and user satisfaction, a simple application that ensured easy, quick and human-error-proof collection, was perused. Its main objective is to be a support for on-site decision making. According to these characteristics, the model has the following features:

1. A single data collection format requiring the input of just a few data associated to each productive unit. Also, it differentiates input information according to the periodicity of registration, and sets up daily, weekly or monthly measurement.
2. It allows for the input and storage of productive units, contractors and non-compliance causes in order to standardize data collection, thus avoiding duplication. When the user inputs production data, the activity, the contractor and the non-compliance cause must be selected from a list. If any of these elements does not exist, it must be created.
3. It carries out all the calculations, eliminating the possibility of human error in data processing.
4. It displays the general results (weekly, monthly or general) obtained from the calculations in graphs or dynamic charts to make reading the information, as well as observe trends easy. Moreover, it allows for the download of measured information in Excel format, which can then be used transversally in other applications.
5. It allows for the measurements to be performed on any mobile device with internet access. In the event such a device is not available, data collection formats can be printed out, and the data will have to be entered manually at a later time.
6. It makes the selection of contractors efficient. Based on the compliance percentage found in the database, the process of selecting contractors will be improved considering their previous compliance with their commitments.
7. It uses the results obtained by the page for the planning and programming of current and future projects.
8. It has a wide database, with a considerable amount of man-hours daily production data. With this information, the daily man-hours average will be available, which can be used to forecast the duration of an activity using realistic data based on rigorous observation instead of theoretical data based on experience or the subjective opinion of the planners.
9. It allows for fast data analysis using the general reports it delivers, through comparisons between projects, between activities and in set time periods, with the purpose of finding the problems emerging at the site and plan strategies to help mitigate them to improve on-site production.

4. Development and Implementation of Productivity DDS

Once the web page had been chosen as the means to measure production rates, the exploration of functions that could of interest to the client was perused. To that end, the interface of the web page was the first deliverable to be designed seeking to verify that the client was pleased with the design and considered whether the functions therein selected at the time were relevant. Such functions were:

- The option to create a new project with its corresponding initial characteristics.
- The option to have a database of the production rates per project.
- The option to divide the factors affecting productivity for each project in 4 groups (factors defined at the beginning of the project, factors to be measured monthly, factors to be measured weekly, factors to be measured daily).

The option to have an Excel downloadable report per project with all the production rates data in a user defined date range reporting the following:

- Total daily production.
- Daily production per contractor.
- Number of workers per contractor.
- Non-compliance causes.
- Daily possible production had non-compliance causes been null.

The option to have a tab listing the company's unified activities, with each activity having its own unit of measurement.

Specifically for factors affecting productivity, the possibility to use a neural network or vector methods to determine the real influence each of these factors could have on the activities measured, was proposed. In spite of the great complexity and the elevated number of field measurements needed to configure the aforementioned networks or methods, the decision was made to do so as it was considered to be a very useful tool for any construction company. The client approved the proposal, and these initial proposals were put on production track for the web page.

In a later meeting, the client was shown the tools approved for implementation. Upon exploring the functionality of the web page, the company expressed some concerns. Hence, the functionality expected by the company was revisited. In the following meeting, a series of general reports on the company production rates was proposed, comprising graphs comparing daily production of an activity across projects. It is of note that at first these reports were built in Excel tables and dynamic graphs in order to test and modify them prior to their inclusion in the application.

The first report executed dealt with average daily production per project. This report shows the real production rate, the maximum production rate and the minimum production rate for a specific activity (see Chart 2).

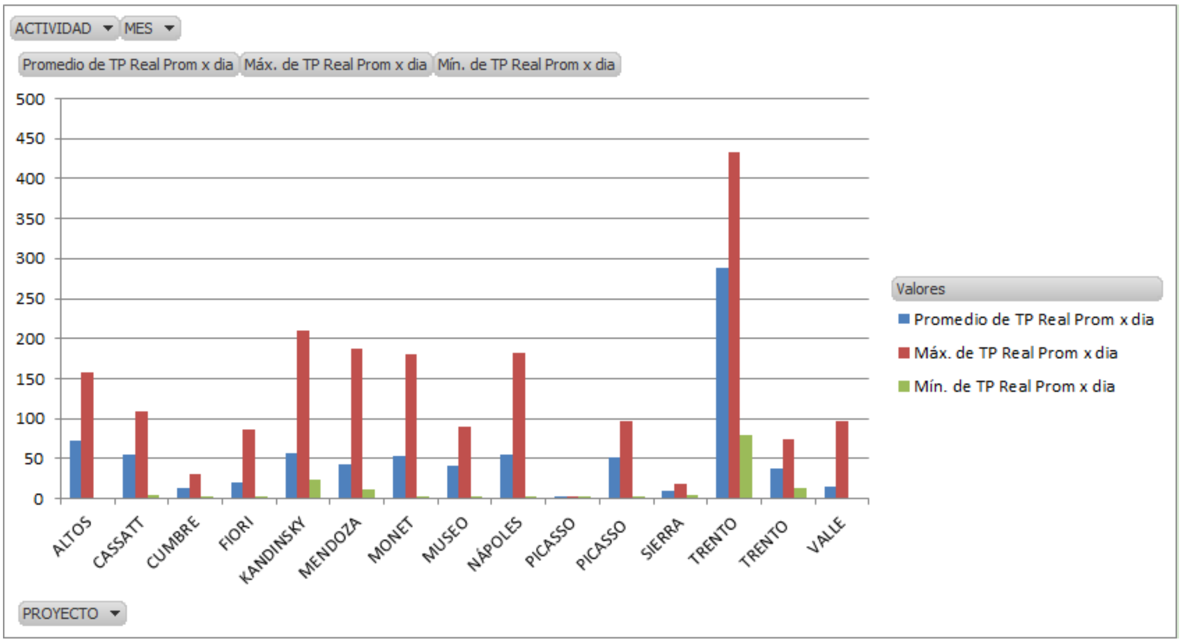

Chart 2: Average Daily Production per Project

The second report executed dealt with the production rate for each activity. This report shows the daily average production rate for each activity using a dynamic table (see Chart 3).

Actividad	Promedio de TP Real Prom x dia
AMARRE VIGAS DE TRANSICIÓN	8,36
CARPINTERÍA DE MADERA	2,29
CLOSETS	1,42
ENCHAPE DE BAÑO	5,64
ENCHAPE DE COCINA	5,53
ENCHAPE LADRILLO	11,17

VENTANERIA	5,71
VENTANERIA T1	10,05
VENTANERIA T2	9,88

Chart 3: Production Rates for each Activity

The third report executed dealt with the monthly average production rates. This report shows the monthly production rate achieved for each activity or in general (see Chart 4).

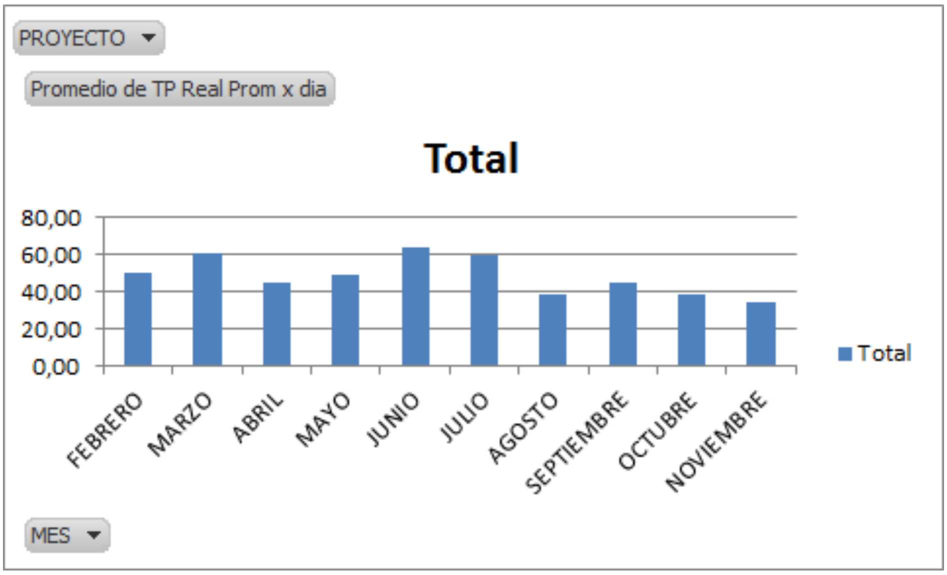

Chart 4: Monthly Production Rates

The fourth report designed dealt with the month-to-month project production rate. This report shows the monthly average production rate for each project (see Chart 5).

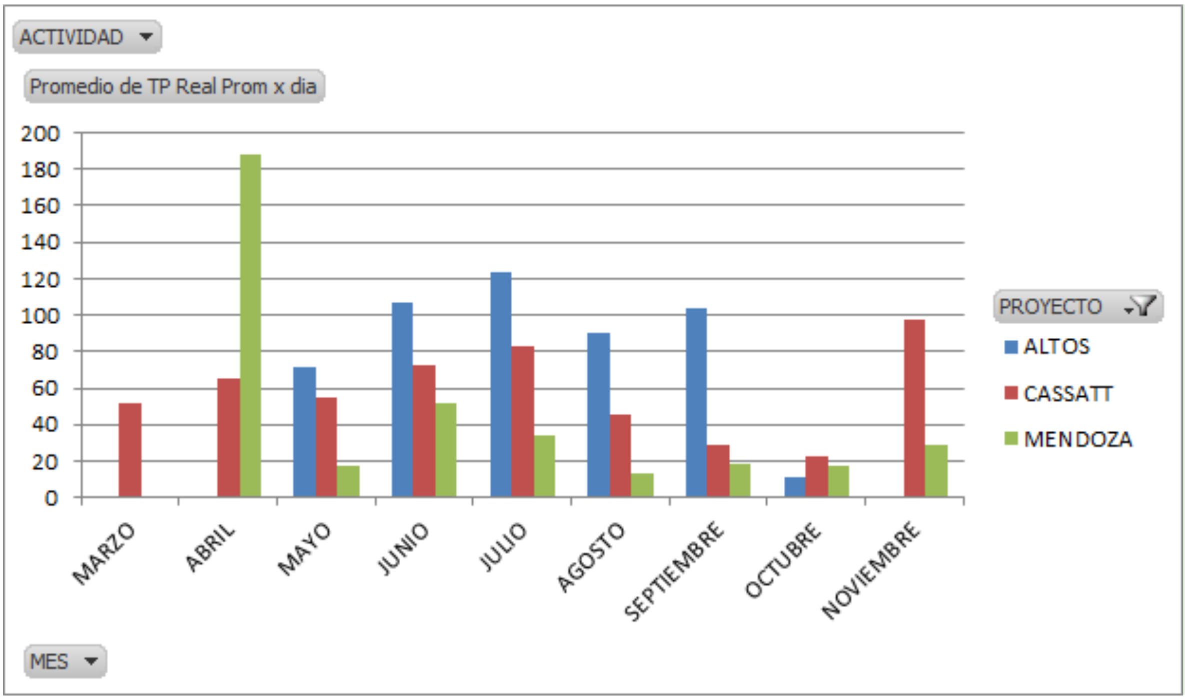

Chart 5: Monthly Production Rate per Project

The fifth report submitted dealt with wasted hours per project. This report showed total hour wastage per project (see Chart 6).

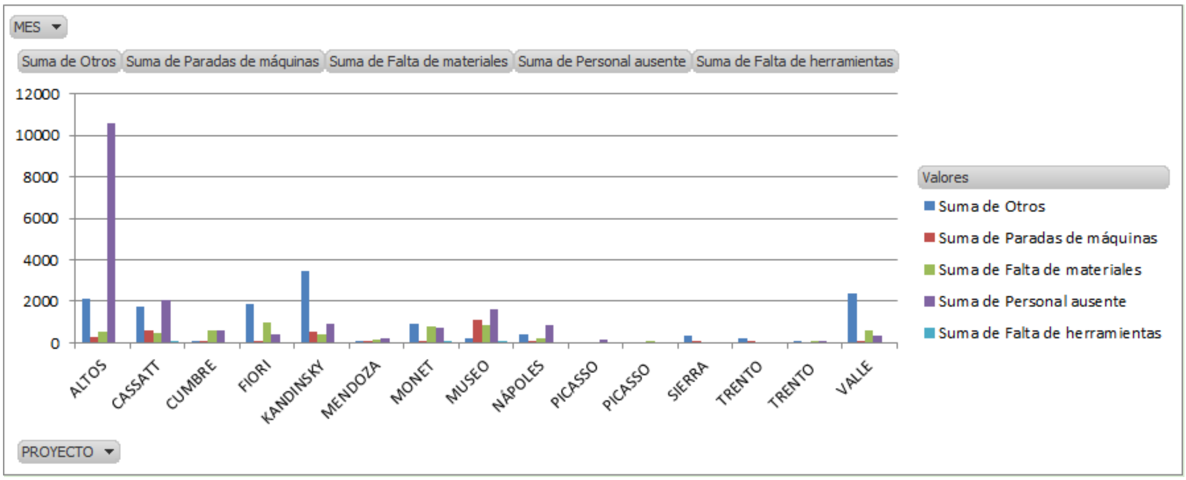

Chart 6: Hour Wastage Average per Project

Once these reports were verified, they were included in the application. This prompted a meeting with the company where several agreements were reached. The company would unify its activities to avoid repetition. Likewise, developers would add the same graphs, but including production per man-hours into the application, in addition to other additional graphs on non-compliance causes per month, and per activity, a graph with the compliance percentage per contractor, and modifications to the format of the graphs. The implementation of these adjustments, including a user manual for the application, satisfied the client's requirements. The manual is included in Appendix (number).

5. Results Obtained

Owing to the foregoing, the DDS allowing for the measurement of activity performance, was developed. In addition to this, the application makes all the calculations and produces general reports for their analysis and consequent improvement of the future company forecasts. This application does not only use the performance of each activity, but also the non-compliance causes and displays compliance percentage, which allows for deeper, more accurate analysis. In order to view the reports, it is necessary to enter the time lapse desired (the software requires a start and an end date). Each of the reports produced by the application shall now be described. See the user manual in Appendix (number) for details on how to produce each report.

5.1. Production Rates per Project (I1.1)

This report shows production rates for each activity differentiated by the different projects created to date. This report includes two graphs. The first shows the Forecasted Production Rates (FPRs), the Measured Production Rates (MPRs), the Maximum Production Rates (MaxPRs) and Minimum Production Rates (MinPR). The second shows compliance percentages (CP) for the activities in each project.

5.2. Real and Forecasted Production Rates per Man-hours (I1.2)

This report shows the FPRs and the MPRs in report I1.1 per man-hours. This report does not include a graph for compliance percentage, as it is the same shown in I1.1.

5.3. General Production Rates (I2.1)

This report shows a chart including the production rates differentiated by project. If no project is selected, the software displays a chart with all created activities measured in the time lapse defined by the user.

5.4. General Production Rates per Man-hours (I2.2.)

This report is similar to I2.1 – General Production Rates, but this one shows production rates per man-hours.

5.5. Weekly or Monthly Activity Production Rates (I4.1)

This report displays daily measured and forecasted average production in months or weeks lapses. It allows selecting a particular project or all projects simultaneously. Additionally, it shows compliance percentages for each month or week.

5.6. Monthly or Weekly Average Real and Forecasted Production Rate per Man-hours (I4.2)

This report is similar to Monthly or Weekly Average Real Production Rate, but this one shows production rates per man-hours. The compliance percentage graph is equal to that in report I4.1.

5.7. Monthly or Weekly Average Real and Forecasted Production Rate (I5.1)

This report shows three graphs. The first graph shows the forecasted production rate. This bar graph shows daily forecasted production for a specified activity in each month or week (depending on the selection). Moreover, daily production per project is differentiated, with each project having an independent bar and color. The second graph shows measured production rate. This graph shows daily average measured production in each project for the specified activity and time lapse. The third graph shows the compliance percentage for the selected activity, in the specified time lapse, in the selected time unit and per project.

5.8. Monthly and Weekly Real and Forecasted Production Rate per Man-hours (I5.2)

This report allows the study of the real and the forecasted average performance of an activity in a specified time lapse. This report is ideal to estimate learning curves and evaluate the impact of measurements taken aimed at increasing productivity.

5.9. Non-compliance Causes per Project (I6.1)

This report shows non-compliance causes per activity in each project. In the event that no activity is selected, the total of non-compliance causes for all activities is displayed. It also allows for the simultaneous selection of several projects for their comparison.

5.10. Non-compliance Causes per Month (I6.2)

This report shows non-compliance causes emerged monthly or weekly. Moreover, the information can be filtered by activity or by project.

5.11. Non-compliance Causes per Activity (I6.3)

This report shows non-compliance causes per activity and the amount of man-hours that production was stopped. This allows to study hour wastage per project and activity, in order to make decisions and see their impact in time.

5.12. Compliance Percentage per Contractor (I10)

This report shows the historic compliance percentage each contractor has displayed in the specified time lapse.

6. Conclusions

This study evidences some of the problem faced by civilian construction work stemming from the lack of an adequate method to collect, process and analyze production data. This makes the use of real data difficult in decision making and future planning processes.

One of the tasks of the Production Data Taker is to check up on the effective advance of the work using the compliance percentage. Comparing the real production rate with the forecasted production rate, the activity's real advance percentage is revealed. This grants better foresight in making decisions affecting the execution of that activity, as well as its predecessors and successors, while preventing errors in intermediate and short-term planning. This allows for reality-adjusted planning to reduce uncertainty regarding a master plan activity, avoiding delays and other problems already identified through the non-compliance causes.

Since the program was designed with the objective of avoiding data collecting mistakes, activity duplication and typing errors were also averted. The software makes all the calculations automatically, which eliminates human error.

In order to make contracting easy, the program allows for the comparing of compliance percentages for each contractor. This lets companies evaluate each contractor and work with those that have greatest compliance with the company. Likewise, the Production Data Taker shall assess whether the actions taken on-site aimed at improving productivity were effective. This will only be achieved if the company devotes the required time to on-site data collection and input, as these are indispensable for the reports to show changes in productivity.

7. Recommendations

- The construction company shall define the degree of specificity for their applications. The same criteria must be applied to all their projects in order to unify the measurements.
- Read the user manual to use the software correctly.
- Inputting information collected prior to the implementation of the program is discouraged, as it can be incomplete or contain unnecessary details for the software.
- The software designed in this study is a pilot software, subject to future improvement. Companies are requested to submit suggestions as they implement the tool.
- A later study on the factors affecting productivity shall be conducted. This study shall define whether the use or a neural network, a vector or another method is convenient. The result of that study is expected to provide arguments for each factor, that is, to experimentally define the factors affecting productivity in the Colombian construction industry.
    - Once the factors affecting productivity are identified, data collection regarding the same is expected, as well as the creation of a database with information relevant to them.
    - The development of a vector method or a neural network is expected in the future, with the aim of mathematically verify the degree at which these factors affect on-site productivity. These methods are expected to provide arguments for each factor, thus aiding in determining which factors are relevant and which are not. In the case of relevant factors, the duration of affected activities can then be adjusted, thus increasing project duration predictability.
    - This information could be used in a later article about the chosen factors affecting productivity, and how to neutralize their negative effects, seeing as some factors cannot be eliminated.
- To learn more about the usage of this tool, click below to download the userguide:

8. Acknowledgments

The writers gratefully acknowledge the important contributions to this research provided by:

- Dr. Jose Luis Ponz-Tienda and Mr. Juan Sebastián Rojas Quintero, professors at University of Los Andes, for their valuable guidance and contribution throughout the development of this research.
- The Cusezar International Group, who provided real data and collaborated in the development of the software, which helped to carry out this research.

Proceedings of the CIB World Building Congress 2016

These proceedings (Volume I - V) bring together papers presented at the **CIB World Building Congress 2016**. The CIB World Building Congresses have for several decades been the leading global events on construction research and innovation.

The theme for CIB World Building Congress 2016 was "Intelligent built environment for life”. It highlights the importance of build environment and its development to the society. This triennial congress focused on the intelligent processes, products and services of construction industry:

- How can research help to improve the contribution of constructed assets to digitalizing world and service needs?
- How will the research community meet emerging new needs of the users?

CIB is an association whose objectives are to stimulate and facilitate international cooperation and information exchange between governmental research institutes in the building and construction sector, with an emphasis on those institutes engaged in technical fields of research. CIB is a world wide network of over 5.000 experts from about 500 member organisations with a research, university, industry or government background, who collectively are active in all aspects of research and innvation for building and construction.
